
Springer Handbook of Electronic and Photonic Materials

Safa Kasap, Peter Capper (Eds.)

With CD-ROM, 930 Figures and 168 Tables

Springer

Springer Handbook of Electronic and Photonic Materials

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical sciences and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes are designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Foreword

The Editors, Authors, and Publisher are to be congratulated on this distinguished volume, which will be an invaluable source of information to all workers in the area of electronic and photonic materials. Having made contributions to earlier handbooks, I am well aware of the considerable, and sustained work that is necessary to produce a volume of this kind. This particular handbook, however, is distinguished by its breadth of coverage in the field, and the way in which it discusses the very latest developments. In such a rapidly moving field, this is a considerable challenge, and it has been met admirably.

Previous handbooks and encyclopaedia have tended to concentrate on semiconducting materials, for the understandable reason of their dominance in the electronics field, and the wide range of semiconducting materials and phenomena that must be covered. Few have been courageous enough to predict future trends, but in 1992 Mahajan and Kimerling attempted this in the Introduction to their Concise Encyclopaedia of Semiconducting Materials and Related Technologies (Pergamon), and foresaw future challenges in the areas of nanoelectronics, low dislocation-density III-V substrates, semi-insulating III-V substrates, patterned epitaxy of III-Vs, alternative dielectrics and contacts for silicon technology, and developments in ion-implantation and diffusion. To a greater or lesser extent, all of these have been proved to be true, but it illustrates how difficult it is to make such a prediction.

Not many people would have thought, a decade ago, that the III-nitrides would occupy an important position in this book. As high melting point materials, with the associated growth problems, they were not high on the list of favourites for light emitters at the blue end of the spectrum! The story is a fascinating one – at least as interesting as the solution to the problem of the short working life of early solid-state lasers at the red end of the spectrum. Optoelectronics and photonics, in general, have seen one of the most spectacular advances over the last decade, and this is fully reflected in the book, ranging from visible light emitters, to infra-red materials. The book covers a wide range of work in Part D, including III-V and II-VI optoelectronic materials and band-gap engineering, as well as photonic glasses, liquid crystals, organic

photoconductors, and the new area of photonic crystals. The whole Part reflects materials for light generation, processing, transmission and detection – all the essential elements for using light instead of electrons.

In the Materials for Electronics part (Part C) the book charts the progress in silicon – overwhelmingly the dominant material for a whole range of electronic functions and circuitry – including new dielectrics and other issues associated with shrinking geometry of circuits and devices to produce ever higher packing densities. It also includes areas rarely covered in other books – thick films, high-temperature electronic materials, amorphous and microcrystalline materials. The existing developments that extend the life of silicon technology, including silicon/germanium alloys, appear too, and raise the question again as to whether the predicted timetable for the demise of silicon has again been declared too early!! Ferroelectrics – a class of materials used so effectively in conjunction with silicon – certainly deserve to be here.

The chapters in Part E (Novel Materials and Selected Applications), break new ground in a number of admirable ways. Most of us are aware of, and frequently use, information recording devices such as CDs, videos, DVDs etc., but few are aware of the materials, or principles, involved. This book describes magnetic information storage materials, as well as phase-change optical recording, keeping us fully up-to-date with recent developments. The chapters also include applications such as solar cells, sensors, photoconductors, and carbon nanotubes, on which such a huge volume of work is presently being pursued worldwide. Both ends of the spectrum from research to applications are represented in chapters on molecular electronics and packaging materials.

A particular strength of this book is that it ranges from the fundamental science (Part A) through growth and characterisation of the materials (Part B) to

Prof. Arthur Willoughby
Materials Research Group,
University of Southampton,
UK

applications (Parts C–E). Virtually all the materials covered here have a wide range of applications, which is one of the reasons why this book is going to be so useful. As I indicated before, few of us will be successful in predicting the future direction and trends,

occupying the high-ground in this field in the coming decade, but this book teaches us the basic principles of materials, and leaves it to us to adapt these to the needs of tomorrow. I commend it to you most warmly.

Preface

Other handbooks in various disciplines such as electrical engineering, electronics, biomedical engineering, materials science, etc. are currently available and well used by numerous students, instructors and professionals. Most libraries have these handbook sets and each contains numerous (at least 50) chapters that cover a wide spectrum of topics within each well-defined discipline. The subject and the level of coverage appeal to both undergraduate and postgraduate students and researchers as well as to practicing professionals. The advanced topics follow introductory topics and provide ample information that is useful to all, beginners and researchers, in the field. Every few years, a new edition is brought out to update the coverage and include new topics.

There has been no similar handbook in electronic and photonic materials, and the present Springer Handbook of Electronic and Photonic Materials (SHEPM) idea grew out of a need for a handbook that covers a wide spectrum of topics in materials that today's engineers, material scientists, physicists, and chemists need. Electronic and photonic materials is a truly interdisciplinary subject that encompasses a number of traditional disciplines such as materials science, electrical engineering, chemical engineering, mechanical engineering, physics and chemistry. It is not unusual to find a mechanical engineering faculty carrying out research on electronic packaging and electrical engineers carrying out characterization measurements on semiconductors. There are only a few established university departments in electronic or photonic materials. In general, electronic materials as a "discipline" appears as a research group or as an interdisciplinary activity within a "college". One could argue that, because of the very fact that it is such an interdisciplinary field, there is a greater need to have a handbook that covers not only fundamental topics but also advanced topics; hence the present handbook.

This handbook is a comprehensive treatise on electronic and photonic materials with each chapter written by experts in the field. The handbook is aimed at senior undergraduate and graduate students, researchers and professionals working in the area of electronic, optoelectronic and photonic materials. The chapters provide the necessary background and up-to-date knowledge

in a wide range of topics. Each chapter has an introduction to the topic, many clear illustrations and numerous references. Clear explanations and illustrations make the handbook useful to all levels of researchers. All chapters are as self-contained as possible. There are both fundamental and advanced chapters to appeal to readers with different backgrounds. This is particularly important for this handbook since the subject matter is highly interdisciplinary. For example, there will be readers with a background (first degree) in chemical engineering and working on semiconductor processing who need to learn the fundamentals of semiconductors physics. Someone with a first degree in physics would need to quickly update himself on materials science concepts such as liquid phase epitaxy and so on. Difficult mathematics has been avoided and, whenever possible, the explanations have been given semiquantitatively. There is a "*Glossary of Defining Terms*" at the end of the handbook, which can serve to quickly find the definition of a term – a very necessary feature in an interdisciplinary handbook.

The editors are very grateful to all the authors for their excellent contributions and for their cooperation in delivering their manuscripts and in the various stages of production of this handbook. Sincere thanks go to Greg Franklin at Springer Boston for all his support and help throughout the long period of commissioning, acquiring the contributions and the production of the handbook. Dr. Werner Skolaut at Springer Heidelberg has very skillfully handled the myriad production issues involved in copy-editing, figure redrawing and proof preparation and correction and our sincere thanks go to him also for all his hard

work in making the handbook attractive to read. He is the most dedicated and efficient editor we have come across.

It is a pleasure to thank Professor Arthur Willoughby for his many helpful suggestions that made this a better handbook. His wealth of experience as editor of the *Journal of Materials Science: Materials in Electronics* played an important role not only in selecting chapters but also in finding the right authors.

Finally, the editors wish to thank all the members of our families (Marian, Samuel and Thomas; and Nicolette) for their support and particularly their endurance during the entire project.

	About the Authors	1291
	Detailed Contents	1307
	Glossary of Defining Terms	1333
	Subject Index	1367

List of Abbreviations

2DEG two-dimensional electron gas

A

AC alternating current
 ACCUFET accumulation-mode MOSFET
 ACRT accelerated crucible rotation technique
 AEM analytical electron microscopes
 AES Auger electron spectroscopy
 AFM atomic force microscopy
 ALD atomic-layer deposition
 ALE atomic-layer epitaxy
 AMA active matrix array
 AMFPI active matrix flat-panel imaging
 AMOLED amorphous organic light-emitting diode
 APD avalanche photodiode

B

b.c.c. body-centered cubic
 BEEM ballistic-electron-emission microscopy
 BEP beam effective pressure
 BH buried-heterostructure
 BH Brooks–Herring
 BJT bipolar junction transistor
 BTEX m-xylene
 BZ Brillouin zone

C

CAIBE chemically assisted ion beam etching
 CB conduction band
 CBE chemical beam epitaxy
 CBED convergent beam electron diffraction
 CC constant current
 CCD charge-coupled device
 CCZ continuous-charging Czochralski
 CFLPE container-free liquid phase epitaxy
 CKR cross Kelvin resistor
 CL cathodoluminescence
 CMOS complementary metal-oxide-semiconductor
 CNR carrier-to-noise ratio
 COP crystal-originated particle
 CP charge pumping
 CPM constant-photocurrent method
 CR computed radiography
 CR-DLTS computed radiography deep level transient spectroscopy
 CRA cast recrystallize anneal
 CTE coefficient of thermal expansion
 CTO chromium(III) trioxalate

CuPc copper phthalocyanine
 CuTTBPc tetra-tert-butyl phthalocyanine
 CV chemical vapor
 CVD chemical vapor deposition
 CVT chemical vapor transport
 CZ Czochralski
 CZT cadmium zinc telluride

D

DA Drude approximation
 DAG direct alloy growth
 DBP dual-beam photoconductivity
 DC direct current
 DCPBH double-channel planar buried heterostructure
 DET diethyl telluride
 DFB distributed feedback
 DH double heterostructure
 DIL dual-in-line
 DIPTe diisopropyltellurium
 DLC diamond-like carbon
 DLHJ double-layer heterojunction
 DLTS deep level transient spectroscopy
 DMCd dimethyl cadmium
 DMF dimethylformamide
 DMOSFET double-diffused MOSFET
 DMS dilute magnetic semiconductors
 DMSO dimethylsulfoxide
 DMZn dimethylzinc
 DOS density of states
 DQE detective quantum efficiency
 DSIMS dynamic secondary ion mass spectrometry
 DTBSe ditertiarybutylselenide
 DUT device under test
 DVD digital versatile disk
 DWDM dense wavelength-division multiplexing
 DXD double-crystal X-ray diffraction

E

EBIC electron beam induced conductivity
 ED electrodeposition
 EDFA erbium-doped fiber amplifier
 EELS electron energy loss spectroscopy
 EFG film-fed growth
 EHP electron–hole pairs
 ELO epitaxial lateral overgrowth
 ELOG epitaxial layer overgrowth
 EM electromagnetic
 EMA effective media approximation

ENDOR electron–nuclear double resonance
 EPD etch pit density
 EPR electron paramagnetic resonance
 ESR electron spin resonance spectroscopy
 EXAFS extended X-ray absorption fine structure

F

FCA free-carrier absorption
 f.c.c. face-centered cubic
 FET field effect transistor
 FIB focused ion beam
 FM Frank–van der Merwe
 FPA focal plane arrays
 FPD flow pattern defect
 FTIR Fourier transform infrared
 FWHM full-width at half-maximum
 FZ floating zone

G

GDA generalized Drude approximation
 GDMS glow discharge mass spectrometry
 GDOES glow discharge optical emission spectroscopy
 GF gradient freeze
 GMR giant magnetoresistance
 GOI gate oxide integrity
 GRIN graded refractive index
 GSMBE gas-source molecular beam epitaxy
 GTO gate turn-off

H

HAADF high-angle annular dark field
 HB horizontal Bridgman
 HBT hetero-junction bipolar transistor
 HDC horizontal directional solidification crystallization
 HEMT high electron mobility transistor
 HF high-frequency
 HOD highly oriented diamond
 HOLZ high-order Laue zone
 HPc phthalocyanine
 HPHT high-pressure high-temperature
 HRXRD high-resolution X-ray diffraction
 HTCVD high-temperature CVD
 HVDC high-voltage DC
 HWE hot-wall epitaxy

I

IC integrated circuit
 ICTS isothermal capacitance transient spectroscopy
 IDE interdigitated electrodes

IFIGS interface-induced gap states
 IFTOF interrupted field time-of-flight
 IGBT insulated gate bipolar transistor
 IMP interdiffused multilayer process
 IPEYS internal photoemission yield spectroscopy
 IR infrared
 ITO indium-tin-oxide

J

JBS junction barrier Schottky
 JFET junction field-effect transistors
 JO Judd–Ofelt

K

KCR Kelvin contact resistance
 KKR Kramers–Kronig relation
 KLN $\text{K}_3\text{Li}_2\text{Nb}_5\text{O}_{12}$
 KTPO KTiOPO_4

L

LB Langmuir–Blodgett
 LD laser diodes
 LD lucky drift
 LDD lightly doped drain
 LEC liquid-encapsulated Czochralski
 LED light-emitting diodes
 LEIS low-energy ion scattering
 LEL lower explosive limit
 LF low-frequency
 LLS laser light scattering
 LMA law of mass action
 LO longitudinal optical
 LPE liquid phase epitaxy
 LSTD laser light scattering tomography defect
 LVM localized vibrational mode

M

MBE molecular beam epitaxy
 MCCZ magnetic field applied continuous Czochralski
 MCT mercury cadmium telluride
 MCZ magnetic field applied Czochralski
 MD molecular dynamics
 MEED medium-energy electron diffraction
 MEM micro-electromechanical systems
 MESFET metal-semiconductor field-effect transistor
 MFC mass flow controllers
 MIGS metal-induced gap states
 ML monolayer
 MLHJ multilayer heterojunction
 MOCVD metal-organic chemical vapor deposition
 MODFET modulation-doped field effect transistor

MOMBE	metalorganic molecular beam epitaxy
MOS	metal/oxide/semiconductor
MOSFET	metal/oxide/semiconductor field effect transistor
MOVPE	metalorganic vapor phase epitaxy
MPc	metallophthalocyanine
MPC	modulated photoconductivity
MPCVD	microwave plasma chemical deposition
MQW	multiple quantum well
MR	magnetoresistivity
MS	metal–semiconductor
MSRD	mean-square relative displacement
MTF	modulation transfer function
MWIR	medium-wavelength infrared

N

NDR	negative differential resistance
NEA	negative electron affinity
NeXT	nonthermal energy exploration telescope
NMOS	n-type-channel metal–oxide–semiconductor
NMP	N-methylpyrrolidone
NMR	nuclear magnetic resonance
NNH	nearest-neighbor hopping
NSA	naphthalene-1,5-disulfonic acid
NTC	negative temperature coefficient
NTD	neutron transmutation doping

O

OLED	organic light-emitting diode
OSF	oxidation-induced stacking fault
OSL	optically stimulated luminescence
OZM	overlap zone melting

P

PAE	power added efficiency
PAni	polyaniline
pBN	pyrolytic boron nitride
Pc	phthalocyanine
PC	photoconductive
PCA	principal component analysis
PCB	printed circuit board
PDMA	poly(methylmethacrylate)/poly(decyl methacrylate)
PDP	plasma display panels
PDS	photothermal deflection spectroscopy
PE	polysilicon emitter
PE BJT	polysilicon emitter bipolar junction transistor
PECVD	plasma-enhanced chemical vapor deposition
PEN	polyethylene naphthalate
PES	photoemission spectroscopy
PET	positron emission tomography
pHEMT	pseudomorphic HEMT

PL	photoluminescence
PM	particulate matter
PMMA	poly(methyl-methacrylate)
POT	poly(<i>n</i> -octyl)thiophene
ppb	parts per billion
ppm	parts per million
PPS	polyphenylsulfide
PPY	polypyrrole
PQT-12	poly[5,5'-bis(3-alkyl-2-thienyl)-2,2'-bithiophene]
PRT	platinum resistance thermometers
PSt	polystyrene
PTC	positive temperature coefficient
PTIS	photothermal ionisation spectroscopy
PTS	1,1-dioxo-2-(4-methylphenyl)-6-phenyl-4-(dicyanomethylidene)thiopyran
PTV	polythienylene vinylene
PV	photovoltaic
PVD	physical vapor transport
PVDF	polyvinylidene fluoride
PVK	polyvinylcarbazole
PVT	physical vapor transport
PZT	lead zirconate titanate

Q

QA	quench anneal
QCL	quantum cascade laser
QCSE	quantum-confined Stark effect
QD	quantum dot
QHE	quantum Hall effect
QW	quantum well

R

RAIRS	reflection adsorption infrared spectroscopy
RBS	Rutherford backscattering
RCLED	resonant-cavity light-emitting diode
RDF	radial distribution function
RDS	reflection difference spectroscopy
RE	rare earth
RENS	resolution near-field structure
RF	radio frequency
RG	recombination–generation
RH	relative humidity
RHEED	reflection high-energy electron diffraction
RIE	reactive-ion etching
RIU	refractive index units
RTA	rapid thermal annealing
RTD	resistance temperature devices
RTS	random telegraph signal

S

SA	self-assembly
SAM	self-assembled monolayers

SAW	surface acoustic wave
SAXS	small-angle X-ray scattering
SCH	separate confinement heterojunction
SCVT	seeded chemical vapor transport
SE	spontaneous emission
SEM	scanning electron microscope
SIMS	secondary ion mass spectrometry
SIPBH	semi-insulating planar buried heterostructure
SIT	static induction transistors
SK	Stranski–Krastanov
SNR	signal-to-noise ratio
SO	small outline

Introduction

Introduction

1 Perspectives on Electronic and Optoelectronic Materials

Tim Smeeton, Oxford, UK

Colin Humphreys, Cambridge, UK

Perspectives

1. Perspectives on Electronic and Optoelectronic Materials

This opening chapter will concentrate on the changes in the world of semiconducting materials and devices over the latter half of the twentieth century. Within this field we have chosen to concentrate on a few developments and cannot claim to cover all of the major areas. What we plan to do is give a sense of perspective of how the science and technology of these materials has come to its current state and to present a brief overview of why certain materials are chosen for particular device applications.

We start by identifying some of the earliest developments in our understanding of electronic materials; follow the development of silicon technology from the first demonstration of the transistor through to today's integrated circuit; track some of the key electronic and optoelectronic uses of the conventional III–V semiconductors; and end with a review of the last decade's explosion of

interest in the III–nitride materials. The band gaps of the semiconductors encountered in this chapter are shown in Fig. 1.1 – a figure which will be frequently referred to in explaining the choice of materials for specific applications.

We sometimes forget how remarkable electronic and optoelectronic materials are. Take the light emitting diode (LED) as an example: an electric current is passed through nothing more than a tiny stack of layers of slightly different compounds and brilliant coloured light is emitted. Of course the stack in question is carefully designed, and there are theories to explain the behaviour, but that should not detract from the initial moment of wonderment that it works at all! Devices from LEDs through to microprocessors containing tens of millions of transistors influence life at the start of this twenty first century to an incalculable extent. These complex devices are only available today because an array of electronic materials have been developed using increasingly sophisticated research methods over the past six decades.

Fig. 1.1 Parameter perspective: band gaps and lattice parameters of selected semiconductors discussed in the text. The important wavelengths for optical storage (CD, DVD and Blu-Ray) and the 1.55 μm used for efficient data transmission through optical fibres are labelled

Most semiconductor-based appliances which affect us every day are made using silicon, but many key devices depend on a number of different compound semiconductors. For example GaP-based LEDs in digital displays; GaAs-based HEMTs which operate in our satellite television receivers; AlGaAs and AlInGaP lasers in our CD and DVD players; and the InP-based lasers delivering the internet and telecommunications along optic fibres.

None of these devices could be manufactured without a basic understanding (either fundamental or

empirical) of the materials science of the components. At the same time the overwhelming reason for scientific study of the materials is to elicit some improvement in the performance of the devices based on them. The rest of this book concentrates on the *materials* more than their *devices* but to give some idea of how a world largely untouched by electronic materials in the 1940s has become so changed by them we will consider the developments in the two fields in parallel in this chapter. Often they are inseparable anyway.

1.1 The Early Years

The exploitation of electronic materials in solid-state devices principally occurred in the second half of the twentieth century but the first serendipitous observations of semiconducting behaviour took place somewhat earlier than this. In 1833, *Faraday* found that silver sulphide exhibited a negative temperature coefficient [1.1]. This property of a decrease in electrical resistivity with increasing temperature was to be deployed in thermistor components a century later. In the 1870s scientists discovered and experimented with the photoconductivity (decreased resistivity of a material under incident light) of selenium [1.2, 3]. Amorphous selenium was to be used for this very property in the first Xerox copying machines of the 1950s.

While these discoveries had limited immediate impact on scientific understanding, more critical progress was made such as Hall's 1879 discovery of what was to become known as the Hall Effect. The discovery of quantum mechanics was of fundamental importance for

our understanding of semiconductors. Based on the advances in quantum theory in the early 1900s a successful theory to explain semiconductor behaviour was formulated in 1931 [1.4, 5]. However, the semiconductors of the 1930s were too impure to allow the theory to be compared with experiment. For example it was believed at the time that silicon, which was to become the archetypal semiconducting material, was a substance belonging to a group of materials which were "good metallic conductors in the pure state and . . . therefore to be classed as metals" [1.5]!

However, a solid theoretical understanding of semiconductors was in place by the 1940s. Hence when the device development focus of the second world war-time research was replaced by peace-time research into the fundamental understanding of real semiconductors, the foundations had been laid for working devices based on elemental semiconductors to be realised.

1.2 The Silicon Age

1.2.1 The Transistor and Early Semiconductor Materials Development

As its name suggests, electronics is about the control of electrons to produce useful properties; electronic materials are the media in which this manipulation takes place. Exactly fifty years after J. J. Thompson had discovered the electron in 1897, mankind's ability to control them underwent a revolution due to the discovery of the transistor effect. It could be said that the world began to change in the final couple of weeks of 1947 when John Bardeen and Walter Brattain used germanium to build and demonstrate the first "semi-conductor

triode" (a device later to be named the point contact transistor to reflect its transresistive properties). This success at Bell Laboratories was obtained within just a few years of the post-war establishment of a research group led by William Shockley focussing on the understanding of semiconducting materials. It was to earn Brattain, Bardeen and Shockley the 1956 Nobel Prize for Physics.

The first point-contact transistor was based around three contacts onto an n-doped germanium block: when a small current passed between the "base" and "emitter", an amplified current would flow between the "collector" and "emitter" [1.6]. The emitter and collector

contacts needed to be located very close to one another (50–250 μm) and this was achieved by evaporating gold onto the corner of a plastic triangle, cutting the film with a razor blade and touching this onto the germanium – the two isolated strips of gold serving as the two contacts [1.7]. At about one centimetre in height, based on relatively impure polycrystalline germanium and adopting a different principle of operation, the device bears barely any resemblance to today's integrated circuit electronics components. Nonetheless it was the first implementation of a solid-state device capable of modulating (necessary for signal amplification in communications) and switching (needed for logic operations in computing) an electric current. In a world whose electronics were delivered by the thermionic vacuum tube, the transistor was immediately identified as a component which could be “employed as an amplifier, oscillator, and for other purposes for which vacuum tubes are ordinarily used” [1.6].

In spite of this, after the public announcement of the invention at the end of June 1948 the response of both the popular and technical press was somewhat muted. It was after all still “little more than a laboratory curiosity” [1.8] and ultimately point-contact transistors were never suited to mass production. The individual devices differed significantly in characteristics, the noise levels in amplification were high and they were rapidly to be superseded by improved transistor types.

A huge range of transistor designs have been introduced from the late 1940s through to today. These successive generations either drew upon, or served as a catalyst for, a range of innovations in semiconductor materials processing and understanding. There are many fascinating differences in device design but from a materials science point of view the three most striking differences between the first point contact transistor and the majority of electronics in use today are the choice of semiconductor, the purity of this material and its crystalline quality. Many of the key electronic materials technologies of today derive from the developments in these fields in the very early years of the post-war semiconductor industry.

Both germanium and silicon had been produced with increasing purity throughout the 1940s [1.9]. Principally because of germanium's lower melting temperature (937 °C compared with 1415 °C) and lower chemical reactivity its preparation had always proved easier and was therefore favoured for the early device manufacture such as the first transistor. However, the properties of silicon make it a much more attractive choice for solid state devices. While germanium is expensive and

rare, silicon is, after oxygen, the second most abundant element. Silicon has a higher breakdown field and a greater power handling ability; its semiconductor band gap (1.1 eV at 300 K; Fig. 1.1) is substantially higher than germanium's (0.7 eV) so silicon devices are able to operate over a greater range of temperatures without intrinsic conductivity interfering with performance.

The two materials competed with one another in device applications until the introduction of novel doping techniques in the mid-1950s. Previously p- and n-doping had been achieved by the addition of dopant impurities to the semiconductor melt during solidification. A far more flexible technique involved the diffusion of dopants from the vapour phase into the solid semiconductor surface [1.10]. It became possible to dope with a degree of two-dimensional precision when it was discovered that silicon's oxide served as an effective mask to dopant atoms and that a photoresist could be used to control the etching away of the oxide [1.11, 12]. Successful diffusion masks could not be found for germanium and it was soon abandoned for mainstream device manufacture. Dopant diffusion of this sort has since been superseded by the implantation of high-energy ions which affords greater control and versatility.

Shockley was always aware that the material of the late 1940s was nothing like pure enough to make reliable high performance commercial devices. Quantum mechanics suggested that to make a high quality transistor out of the materials it was necessary to reduce the impurity level to about one part in 10^{10} . This was a far higher degree of purity than existed in any known material. However, William Pfann, who worked at Bell Laboratories, came up with the solution. He invented a technique called zone-refining to solve this problem, and showed that repeated zone refining of germanium and silicon reduced the impurities to the level required. The work of *Pfann* is not widely known but was a critical piece of materials science which enabled the practical development of the transistor [1.13, 14].

At a similar time great progress was being made in reducing the crystalline defect density of semiconducting materials. Following initial hostility by some of the major researchers in the field it was rapidly accepted that transistor devices should adopt single crystalline material [1.15]. Extended single crystals of germanium several centimetres long and up to two centimetres in diameter [1.15, 16] and later similar silicon crystals [1.17] were produced using the *Czochralski* technique of pulling a seed crystal from a high purity melt [1.18]. The majority of material in use today is derived from this route. To produce silicon with

the very lowest impurity concentration, an alternative method called float zoning was developed where a polycrystalline rod was converted to a single crystal by the passage of a surface tension confined molten zone along its length [1.19–21]. No crucible is required in the process so there are fewer sources of impurity contamination. Float zoning is used to manufacture some of the purest material in current use [1.22]. The early Czochralski material contained dislocation densities of 10^5 – 10^6 cm⁻² but by the start of the 1960s dislocation free material was obtained [1.23–26]. Initially most wafers were on the silicon (111) plane, which was easiest to grow, cut and polish [1.27]. For field-effect devices, which are discussed below, use of the (100) plane was found to offer preferable properties so this was introduced in the same decade. The impurity concentration in dislocation-free silicon has been continually reduced up to the present day and wafer diameters have increased almost linearly (though accelerating somewhat in recent years) from about 10 mm in the early 1960s to the “dinner plate” 300 mm today [1.22]. These improvements represent one of the major achievements in semiconductor materials growth and processing.

A series of generations of transistors followed in rapid succession after Brattain and Bardeen’s first triumph. Here we only mention a few of the major designs whose production have traits in common with technology today. Early in 1948 *Shockley* developed a detailed formulation of the theory of p–n junctions that concluded with the conception of the junction transistor [1.28, 29]. This involved a thin n-doped base layer sandwiched between p-doped emitter and collector layers (or vice versa). This p–n–p (n–p–n) structure is the simplest form of the bipolar transistor (so-called because of its use of both positive and negative charge carriers), a technology which remains important in analogue and high-speed digital integrated circuits today. In April 1950, by successively adding arsenic and gallium (n- and p-type dopants respectively) impurities to the melt, n–p–n junction structures with the required p-layer thickness (≈ 25 μ m) were formed from single crystal germanium. When contacts were applied to the three regions the devices behaved much as expected from *Shockley’s* theory [1.28, 30]. Growth of junction transistors in silicon occurred shortly afterwards and they entered production by Texas Instruments in 1954 [1.15].

By the later years of the 1950s, the diffusion doping technique was used to improve the transistor’s speed response by reducing the thickness of the base layer in the

diffused base transistor [1.31]. This began the trend of manufacturing a device in situ on a substrate material so in a sense it was the foundation for all subsequent micro-electronic structures. Soon afterwards, epitaxial growth techniques were introduced [what would today be described as vapour phase epitaxy (VPE)] which have since become central to both silicon and compound semiconductor technology. Gas phase precursors were reacted to produce very high quality and lightly doped crystalline silicon on heavily doped substrate wafers to form epitaxial diffused transistors. Since the collector contact was made through the thickness of the wafer, the use of highly doped (low resistance) wafers reduced the series resistance and therefore increased the frequency response [1.32].

For some years the highest performance devices were manufactured using the so-called “mesa” process where the emitter and diffused base were raised above the collector using selective etching of the silicon [1.28]. The planar process (which is still at the heart of device production today) was subsequently developed, in which the p–n junctions were all formed inside the substrate using oxide masking and diffusion from the surface. This resulted in a flat surface to which contacts could be made using a patterned evaporated film [1.33]. This processing technique was combined with some exciting thoughts at the end of the 1950s and led to the application of transistor devices and other components in a way which was to transform the world: the integrated circuit.

1.2.2 The Integrated Circuit

With the benefit of hindsight, the integrated circuit concept is quite simple. The problem faced by the electronics industry in the 1950s was the increasing difficulty of physically fitting into a small device all of the discrete electronic components (transistors, diodes, resistors and capacitors), and then connecting them together. It was clear that this problem would eventually limit the complexity, reliability and speed of circuits which could be created. Transistors and diodes were manufactured from semiconductors but resistors and capacitors were best formed from alternative materials. Even though they would not deliver the levels of performance achievable from the traditional materials, functioning capacitors and resistors *could* be manufactured from semiconductors so, in principle, all of the components of a circuit could be prepared on a single block of semiconducting material. This reasoning had been proposed by Englishman G.W.A. Dummer at

a conference in 1952 [1.34] but small-scale attempts to realise circuits had failed, largely because they were based on connecting together layers in grown-junction transistors [1.35]. In 1958, however, Jack Kilby successfully built a simple oscillator and “flip-flop” logic circuits from components formed in situ on a germanium block and interconnected to produce circuits. He received the Nobel Prize in 2000 for “his part in the invention of the integrated circuit”.

Kilby’s circuits were the first built on a single semiconductor block, but by far the majority of the circuit’s size was taken up by the wires connecting together the components. Robert Noyce developed a truly integrated circuit (IC) in the form that it was later to be manufactured. While Kilby had used the mesa technique with external wiring, Noyce applied the planer technique to form transistors on silicon and photolithographically defined gold or aluminium interconnects. This was more suited to batch processing in production and was necessary for circuits with large numbers of components.

Most integrated circuits manufactured today are based around a transistor technology distinct from the bipolar device used in the first chips but one still dating from the 1960s. In 1960 the first metal oxide semiconductor field effect transistor (MOSFET) was demonstrated [1.36]. In this device a “gate” was deposited onto a thin insulating oxide layer on the silicon. The application of a voltage to the gate resulted in an inversion layer in the silicon below the oxide thereby modifying the conducting channel between “source” and “drain” contacts. This structure was a p-MOS device (current transfer between the collector and emitter was by hole conduction) grown on (111) silicon using an aluminium gate. Earlier attempts at such a device had failed because of trapped impurities and charges in the gate oxide – this new structure had reduced the density of these to below tolerable levels but the device still could not compete with the bipolar transistors of its time [1.27]. By 1967, however, (100) silicon (which offered lower densities of states at the Si/SiO₂ interface) was used together with a polycrystalline silicon gate to construct a more effective and more easily processed device with advantages over the bipolar transistor. In the early 1970s the n-MOS device, which was even less tolerant to the positive gate oxide charges, was realised thanks to much improved cleanliness in the production environment. With conduction occurring by the transfer of electrons rather than holes these were capable of faster operation than similar p-MOS structures (the mobility of electrons in silicon is about three times that of

holes). By the 1980s, these two devices were combined in the complementary MOS (CMOS) device which afforded much lower power consumption and simplified circuit design [1.37]. This remains the principal structure used in microelectronics today. Of course now it is much smaller and significantly faster thanks to a range of further advances. These include improved control of the doping and oxidation of silicon and developments in optical lithographic techniques [1.37]. The minimum dimension of components which can be lithographically patterned on an integrated circuit is ultimately limited by the wavelength of radiation used in the process and this has continually been decreased over the past few decades. In the late 1980s wavelengths of 365 nm were employed; by the late 1990s 248 nm were common and today 193 nm is being used. Research into extreme ultra-violet lithography at 13.5 nm may see this being adopted within the next decade enabling feature sizes perhaps as low as 25 nm.

Though ICs implementing CMOS devices are the foundations for computing, silicon-based bipolar transistors maintain a strong market position today in radio frequency applications. In particular germanium is making something of a comeback as a constituent of the latest generation of SiGe bipolar devices [1.38]. The combination of the two forms of technology on a single chip (BiCMOS) offers the potential for computing and communications to be integrated together in the wireless devices of the coming decade.

The development in complexity and performance of silicon devices, largely due to materials science progress, is unparalleled in the history of technology. Never before could improvements be measured in terms of a logarithmic scale for such a sustained period. This is often seen as the embodiment of “Moore’s Law”. Noting a doubling of the number of components fitted onto integrated circuits each year between 1959 and 1965, *Moore* predicted that this rate of progress would continue until at least ten years later [1.39]. From the early 1970s, a modified prediction of doubling the number of components every couple of years has been sustained to the current day. Since the goals for innovation have often been defined assuming the continuation of the trend, it should perhaps be viewed more as a self-fulfilling prophecy. A huge variety of statistics relating to the silicon microelectronics industry follow a logarithmically scaled improvement from the late 1960s to the current day: the number of transistors shipped per year (increasing); average transistor price (decreasing); and number of transistors on a single chip (increasing) are examples [1.40]. The final member of this list is

Fig. 1.2 The realisation of Moore's law by commercial Intel® processors: The logarithmic increase in the number of transistors in each processor chip

plotted in Fig. 1.2. A graphic example of the continuous scaling down of IC component dimensions is the reduction in the thickness of the MOSFET gate insulator. Figure 1.3 shows high-resolution transmission electron microscopy images of typical commercial devices since the mid-1990s: improved device performance has pre-

Fig. 1.3 The relentless march to zero thickness. HRTEM images of SiO_2 gate oxide thickness used in personal computers (After [1.41] with permission from the Materials Research Society). (Courtesy of Prof D.A. Muller)

dominately been achieved by reducing all dimensions of the IC components. With state-of-the-art gates now approaching the sub-nanometre thicknesses at which SiO_2 breaks down as an insulator, it is clear that achieving device performance by scaling alone cannot be sustained for much longer. Overcoming this limit, perhaps through the substitution of SiO_2 for a material with a higher dielectric constant, is one of the major challenges in silicon IC research today.

1.3 The Compound Semiconductors

It has been said that silicon is to electronics what steel is to mechanical engineering [1.42]. Steel is very effectively used for most of the world's construction but there are some tasks which it is incapable of performing and others for which alternative structural materials are better suited. In the same way there are some crucial applications – such as optoelectronics and very high speed electronics – that silicon cannot usually deliver but which a wide range of compound semiconductors are better equipped to perform.

Silicon's band gap is indirect (an electron-hole recombination across the band gap must be accompanied by an interaction with a phonon in the lattice) which severely limits the potential efficiency of light emission from the material. Many of the important compound semiconductors, such as the alloys $\text{Al}_x\text{Ga}_{1-x}\text{As}$, $\text{In}_x\text{Ga}_{1-x}\text{N}$, $\text{Al}_y\text{Ga}_{1-y}\text{N}$, and $\text{Al}_x\text{In}_y\text{Ga}_{1-x-y}\text{P}$ exhibit direct band gaps (no phonon interaction is required) so can efficiently emit brilliant light in light emitting diodes (LEDs) and laser diodes. Furthermore, in these alloy

systems, where the band gap can be adjusted by changing the composition, there is a means of selecting the energy released when an electron and hole recombine across the gap and therefore controlling the wavelength of the photons emitted. From the $\text{Al}_x\text{In}_y\text{Ga}_{1-x-y}\text{As}$ and $\text{Al}_y\text{In}_x\text{Ga}_{1-x-y}\text{N}$ alloy systems there is, in principle, a continuous range of direct band gaps from deep in the infra red (InAs; $\lambda = 3.5 \mu\text{m}$) to far into the ultraviolet (AlN; $\lambda = 200 \text{ nm}$). The semiconductor band gaps of these materials and the corresponding photon wavelengths are put into context with the visible spectrum in Fig. 1.1.

Compounds are also very useful in high speed electronics applications. One of the determining factors in the speed of a transistor is the velocity of the charge carriers in the semiconductor. In GaAs the electron drift velocity is much higher than in silicon so its transistors are able to operate at significantly higher frequencies. The electron velocity in InAs is higher still. Furthermore, in the same way that silicon was preferred to

germanium, devices manufactured using semiconductors such as GaN, which have much wider band gaps than silicon (3.4 eV compared with 1.1 eV), are capable of operating in much higher temperature environments.

Aside from these advantageous properties of compound semiconductors, the use of different alloy compositions, or totally different semiconductors, in a single device introduces entirely new possibilities. In silicon, most device action is achieved by little more than careful control of dopant impurity concentrations. In structures containing thin layers of semiconductors with different band gaps (heterostructures) there is the potential to control more fundamental parameters such as the band gap width, mobilities and effective masses of the carriers [1.42]. In these structures, important new features become available which can be used by the device designer to tailor specific desired properties. Hebert Kroemer and Zhores Alferov shared the Nobel prize in 2000 “for developing semiconductor heterostructures used in high-speed- and opto-electronics”.

We will mainly consider the compounds formed between elements in Group III of the periodic table and those in Group V (the III–V semiconductors); principally those based around GaAs and InP which were developed over much of the last forty years, and GaN and its related alloys which have been most heavily studied only during the last decade. Other families are given less attention here though they also have important applications (for example the II–VI materials in optoelectronic applications). It can be hazardous to try and consider the “compound semiconductors” as a single subject. Though lessons can be learnt from the materials science of one of the compounds and transferred to another, each material is unique and must be considered on its own (that is, of course, the purpose of the specialised chapters which follow in this handbook!).

It is worth repeating that the power of the compound semiconductors lies in their use as the constituent layers in heterostructures. The principal contribution from chemistry and materials science to enable successful devices has been in the manufacture of high-quality bulk single crystal substrates and the creation of techniques to reliably and accurately produce real layered structures on these substrates from the plans drawn up by a device theorist. In contrast to silicon, the compound semiconductors include volatile components so encapsulation has been required for the synthesis of low-defect InP and GaAs substrates such as in the liquid encapsulated Czochralski technique [1.43, 44]. The size and crystalline quality of these substrates lag some way behind those available in silicon. Crucial to the commerciali-

sation of electronic and optoelectronic heterostructures were the improvements over the last few decades in the control of epitaxial growth available to the crystal grower. The first successful heterostructures were manufactured using deposition onto a substrate from the liquid phase (liquid phase epitaxy; **LPE**) – “a beautifully simple technology but with severe limitations” [1.42]. However, the real heterostructure revolution had to wait for the 1970s and the introduction of molecular beam epitaxy (**MBE**) and metalorganic chemical vapour deposition (**MOCVD**) – also known as metalorganic vapour phase epitaxy (**MOVPE**) provided that the deposition is epitaxial.

MBE growth occurs in an ultra-high vacuum with the atoms emitted from effusion cells forming “beams” which impinge upon, and form compounds at the substrate surface. It derives from pioneering work at the start of the 1970s [1.45]. **MOCVD** relies on chemical reactions occurring on the substrate involving metalorganic vapour phase precursors and also stems from initial work at this time [1.46]. In contrast to **LPE**, these two techniques permit the combination of a wide range of different semiconductors in a single structure and offer a high degree of control over the local composition, in some cases on an atomic layer scale. The successful heterostructure devices of the late 1970s and 1980s would not have been achievable without these two tools and they still dominate III–V device production and research today.

1.3.1 High Speed Electronics

The advantages of the III–V materials over silicon for use in transistors capable of operating at high frequencies were identified early in the semiconductor revolution [1.47]. Shockley’s first patent for p-n junction transistors had included the proposal to use a wide-gap emitter layer to improve performance and in the 1950s *Kroemer* presented a theoretical design for a heterostructure transistor [1.48]. Some years later the structure of a GaAs metal semiconductor **FET** (**MESFET**) was proposed and realised soon afterwards [1.49, 50]. In these devices a Schottky barrier surface potential was used to modulate the conductivity of the GaAs channel. One of the earliest applications of the III–V’s was as low noise amplifiers in microwave receivers which offered substantial improvements relative to the silicon bipolar transistors of the time. The devices were later used to demonstrate sub-nanosecond switching in monolithic digital **ICs** [1.51]. Today they form the core of the highest speed digital circuits and are used in

high speed electronics in microwave radar systems and wireless communications which incorporate monolithic integrated circuits.

For at least 30 years there have been repeated attempts to replicate the **MOSFET**, the dominant transistor form in silicon **ICs**, on GaAs material. These attempts have been frustrated by the difficulty of reproducibly forming a high quality stoichiometric oxide on GaAs. In direct analogy with the initial failure of constructing working **n-MOSFETs** on silicon, the GaAs devices have consistently been inoperable because of poor quality gate oxides with a high density of surface states at the GaAs-insulator interface [1.44]. One of the research efforts focussed on realising this device was, however, to be diverted and resulted in the discovery of probably the most important III–V electronic device: the high electron mobility transistor (**HEMT**).

The background to this invention lies in the beautiful concept of modulation doping of semiconductors which was first demonstrated in 1978 [1.52]. One of the tenets of undergraduate semiconductor courses is the demonstration that as the dopant density in a semiconductor increases, the mobility of the carriers is reduced because the carriers are scattered more by the ionised dopants. It was found that in a multilayer of repeating **n-AlGaAs** layers and undoped GaAs layers, the electrons supplied by donor atoms in the AlGaAs moved into the adjacent potential wells of the lower-band gap GaAs layers. In the GaAs these suffered from substantially less ionised impurity scattering and therefore demonstrated enhanced mobility.

While working in a group attempting to create GaAs **MOSFETs** (and seemingly despairing at the task! [1.53]), *Mimura* heard of these results and conceived of a field effect transistor where the conducting channel exploited the high mobility associated with a modulation doped structure. In essence, a doped AlGaAs layer was formed above the undoped GaAs channel of the transistor. Donated carriers gathered in the GaAs immediately below the interface where they did not suffer from as much ionised impurity scattering and so their mobility would approach that of an ultra-pure bulk semiconductor. The current was conducted from the source to the drain by these high mobility carriers and so the devices were able to operate in higher frequency applications [1.53]. Realisation of the structure required a very abrupt interface between the GaAs and AlGaAs and was considered beyond the capability of **MOCVD** of the time [1.53]. However, following the advances made in **MBE** procedures during the 1970s the structure was achieved by that technique within a few months of

the original conception [1.53, 54]. The first operational **HEMT** chips were produced on 24th December 1980: by pleasing coincidence this was the anniversary of Brattain and Bardeen's demonstration of their point contact resistor to the management of Bell labs in 1947! Structures based on the same principle as Mimura's device were realised in France very shortly afterwards [1.55].

The commercialisation of the **HEMT** became significant in the late 1980s thanks to broadcasting satellite receivers. The improved performance of the devices compared with the existing technology allowed the satellite parabolic dish size to be reduced by at least a factor of two. Structures similar to these have since played a crucial role in the massive expansion in mobile telephones.

The evolution in **HEMT** structures since the early 1980s is a fine example of how fundamental compound semiconductor properties have been exploited as the technology has become available to realise new device designs. The electron mobility in InAs is much higher than in GaAs and rises as the indium content in $\text{In}_x\text{Ga}_{1-x}\text{As}$ is increased [1.56]. The introduction of an InGaAs (as opposed to GaAs) channel to the **HEMT** structure resulted both in increased electron mobility and a higher density of carriers gathering from the doped AlGaAs layer (because of the larger difference in energy between the conduction band minima of InGaAs and AlGaAs than between GaAs and AlGaAs). This so called pseudomorphic **HEMT** (**pHEMT**) demonstrates state of the art power performance at microwave and millimetre wave frequencies [1.43]. The indium content and thickness of the channel is limited by the lattice mismatch with the GaAs (Fig. 1.1). If either is increased too much then misfit dislocations are formed within the channel. The restriction is reduced by growing lattice matched structures on InP, rather than GaAs, substrates. $\text{Al}_{0.48}\text{In}_{0.52}\text{As}$ and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ are both lattice matched to the InP (Fig. 1.1) and their conduction band minimum energies are well separated so that in the InGaAs below the interface between the two compounds a high density of electrons with a very high mobility is formed. Compared with the **pHEMTs** these InP based **HEMTs** exhibit significant improvements, have been shown to exhibit gain at over 200 GHz and are established as the leading transistor for millimetre-wave low noise applications such as radar [1.43].

1.3.2 Light Emitting Devices

LEDs and laser diodes exploit the direct band gap semiconductors to efficiently convert an electric current into

photons of light. Work on light emission from semiconductor diodes was carried out in the early decades of the twentieth century [1.57] but the start of the modern era of semiconductor optoelectronics traces from the demonstration of LED behaviour and lasing from p-n junctions in GaAs [1.58, 59] and $\text{GaAs}_{1-x}\text{P}_x$ [1.60]. The efficiency of these LEDs was low and the lasers had large threshold currents and only operated at low temperatures. A year later, in 1963, *Kroemer* and *Alferov* independently proposed the concept of the double heterostructure (DH) laser [1.61, 62]. In the DH device, a narrow band gap material was to be sandwiched between layers with a wider gap so that there would be some degree of confinement of carriers in the “active layer”. By the end of the decade DH devices had been constructed which exhibited continuous lasing at room temperature [1.63, 64]. Alferov’s laser was grown by LPE on a GaAs substrate with a $0.5\text{ }\mu\text{m}$ GaAs active layer confined between $3\text{ }\mu\text{m}$ of $\text{Al}_{0.25}\text{Ga}_{0.75}\text{As}$ on either side. The launch of the Compact Disc in 1982 saw this type of device, or at least its offspring, becoming taken for granted in the households of the world.

One of the major challenges in materials selection for heterostructure manufacture has always been avoiding the formation of misfit dislocations to relieve the strain associated with lattice parameter mismatch between the layers. $\text{Al}_x\text{Ga}_{1-x}\text{As}$ exhibits a direct band gap for $x < 0.45$ and the early success and sustained dominance of the AlGaAs/GaAs system derives significantly from the very close coincidence of the AlAs and GaAs lattice parameters ($5.661\text{ }\text{\AA}$ and $5.653\text{ }\text{\AA}$ – see Fig. 1.1). This allows relatively thick layers of AlGaAs with reasonably high aluminium content to be grown lattice matched onto GaAs substrates with no misfit dislocation formation. The use of the quaternary alloy solid solution $\text{In}_x\text{Ga}_{1-x}\text{As}_y\text{P}_{1-y}$ was also suggested in 1970 [1.63] to offer the independent control of lattice parameters and band gaps. Quaternaries based on three Group III elements have since proved very powerful tools for lattice matching within heterostructures. $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$ was found to be almost perfectly lattice matched to GaAs and additionally have a very similar thermal expansion coefficient (which is important to avoid strain evolution when cooling after growth of heteroepitaxial layers at high temperatures). By varying x in this compound, direct band gaps corresponding to light between red and green could be created [1.65]. Lasers based on this alloy grown by MOCVD are a common choice for the red wavelengths (650 nm) used in DVD reading.

Obtaining lattice matching is not so crucial for layers thinner than the critical thickness for dislocation

production and can be less of an issue these days because of probably the most important development in the history of optoelectronic devices: the introduction of the quantum well. In some ways a quantum well structure is an evolution of the double heterostructure but with a very much thinner active layer. It is the chosen design for most solid state light emitting devices today. With the accurate control available from MBE or MOCVD, and following from some early work on superlattices [1.66], very thin layers of carefully controlled composition could be deposited within heterostructure superlattice stacks. It became possible to grow GaAs layers much less than 10 nm thick within AlGaAs–GaAs heterostructures. The carriers in the GaAs were found to exhibit quantum mechanical confinement within the one dimensional potential well [1.67, 68]. Lasing from GaAs/ $\text{Al}_{0.2}\text{Ga}_{0.8}\text{As}$ quantum wells was reported the following year, in 1975, [1.69] but it was a few years before the performance matched that achievable from DH lasers of the time [1.70] and the quantum well laser was further advanced to significantly outperform the competition by researchers in the 1980s [1.71].

The introduction of heterostructures with layer thicknesses on the nanometre scale represents the final stage in scaling down of these devices. Similarly Brattain and Bardeen’s centimetre-sized transistor has evolved into today’s microprocessors with sub-micron FETs whose gate oxide thicknesses are measured in Angstroms. Throughout this evolution, materials characterisation techniques have contributed heavily to the progress in our understanding of electronic materials and deserve a brief detour here. As the dimensions have been reduced over the decades, the cross-sectional images of device structures published in the literature have changed from a period where optical microscopy techniques were sufficient [1.31] to a time when scanning electron microscopy (SEM) images were used [1.70] and to today’s high resolution transmission electron microscopy (TEM) analysis of ultra-thin layers (e.g. Fig. 1.3). For each new material family, understanding of defects and measurement of their densities (e.g. by TEM and X-ray topography) have contributed to improvements in quality. Huge improvements in X-ray optics have seen high-resolution X-ray diffraction techniques develop to become a cornerstone of heterostructure research and production quality control [1.72]. Scanning-probe techniques such as scanning tunnelling and atomic force microscopy have become crucial to the understanding of MBE and MOCVD growth. Chemically sensitive techniques such as secondary ion mass spectroscopy and Rutherford

Fig. 1.4 Annular dark field-scanning transmission electron microscope (ADF-STEM) image of Sb-doped Si. The undoped region (*right*) shows atomic columns of uniform intensity. The brightest columns in the doped region (*left*) contain at least one Sb atom. The image is smoothed and background subtracted (After [1.76], with permission Elsevier Amsterdam). (Courtesy of Prof D.A. Muller)

backscattering have improved to provide information on doping concentrations and compositions in layered structures with excellent depth resolution. Meanwhile recently developed techniques such as energy-filtered TEM [1.73] afford chemical information at extremely high spatial resolutions. The characterisation of doping properties is also coming of age with more quantitative measurement of dopant contrast in the SEM [1.74], analysis of biased junctions in situ in the TEM [1.75] and the recent exciting demonstration of imaging of single impurity atoms in a silicon sample using scanning TEM, Fig. 1.4. The materials characterisation process remains a very important component of electronic materials research.

Two commercial-product oriented aims dominate semiconductor laser research: the production of more effective emitters of infra-red wavelengths for transmission of data along optic fibres; and the realisation of shorter wavelength devices for reading optical storage media. In the first of these fields devices based on InP have proven to be extremely effective because of its fortuitous lattice parameter match with other III–V alloys which have band gaps corresponding to the low-absorption “windows” in optic fibres. While remaining lattice matched to InP, the $\text{In}_x\text{Ga}_{1-x}\text{As}_y\text{P}_{1-y}$ quater-

nary can exhibit band gaps corresponding to infra-red wavelengths of 1.3 μm and 1.55 μm at which conventional optic fibres absorb the least of the radiation (the absolute minimum is for 1.55 μm). Room temperature continuous lasing of 1.1 μm radiation was demonstrated from the material in 1976 [1.77] and InP based lasers and photodiodes have played a key role in the optical communications industry since the 1980s [1.43].

We have already mentioned the AlGaAs infra-red ($\lambda = 780\text{ nm}$) emitters used to read compact discs and the AlGaInP red ($\lambda = 650\text{ nm}$) devices in DVD readers (see Fig. 1.1). As shorter wavelength lasers have become available the optical disc’s surface pits (through which bits of data are stored) could be made smaller and the storage density increased. Though wide band gap II–VI compounds, principally ZnSe, have been researched for many decades for their potential in green and blue wavelengths, laser operation in this part of the visible spectrum proved difficult to realise [1.78]. In the early 1990s, following improvements in the p-doping of ZnSe, a blue-green laser was demonstrated [1.79] but such devices remain prone to rapid deterioration during operation and tend to have lifetimes measured in, at most, minutes. However, also in the early years of the 1990s, a revolution began in wide band gap semiconductors which is ongoing today: the exploitation of GaN and its related alloys $\text{In}_x\text{Ga}_{1-x}\text{N}$ and $\text{Al}_y\text{Ga}_{1-y}\text{N}$. These materials represent the future for optoelectronics over a wide range of previously inaccessible wavelengths and the next generation of optical storage, the “Blu-ray” disc, will be read using an InGaN blue-violet laser ($\lambda = 405\text{ nm}$).

1.3.3 The III-Nitrides

The relevance of the $\text{In}_x\text{Ga}_{1-x}\text{N}$ alloy for light emitting devices is clear from Fig. 1.1. The InN and GaN direct band gaps correspond to wavelengths straddling the visible spectrum and the alloy potentially offers access to all points in-between. The early commercially successful blue light emitters were marketed by Nichia Chemical Industries following the research work of *Nakamura* who demonstrated the first InGaN DH LEDs [1.80] and blue InGaN quantum well LEDs and laser diodes soon after [1.81]. Since this time the global research interest in the GaN material family has expanded rapidly and the competing technology (SiC and ZnSe for blue LEDs and lasers respectively) has largely been replaced.

The development of the III-nitride materials has much in common with the early research of other III–V systems. For example MOCVD and MBE technology

could be adapted for the nitride systems (the former has to date been more suited for creating optical devices) and one of the obstacles limiting early device development was achieving sufficiently high p-type doping. However, in some ways they are rather different from the other compound semiconductors. It is important to realise that while all III–Vs mentioned previously share the same cubic crystallographic structure, the nitrides most readily form in a hexagonal allotrope. Most significant in terms of device development over the past decade has been the difficulty in obtaining bulk GaN substrates. Due to the very high pressures necessary to synthesise the compound only very small pieces of bulk GaN have been produced and though they have been used to form functioning lasers [1.82] they remain unsuited as yet to commercial device production. There has consequently been a reliance on heavily lattice mismatched heteroepitaxial growth.

Many materials have been used as substrates for GaN growth. These include SiC, which has one of the lowest lattice mismatches with the nitride material and would be more widely used if it was less expensive, and silicon, which has considerable potential as a substrate if problems associated with cracking during cooling from the growth temperature can be overcome (there is a large difference between the thermal expansion coefficients of GaN and silicon). The dominant choice, however, remains sapphire (α -Al₂O₃) which itself is by no means ideal: it is electrically insulating (so electrical contacts cannot be made to the device through the substrate material) and, most significantly, has a lattice mismatch of $\approx 16\%$ with the GaN [1.83]. This mismatch is relieved by the formation of misfit dislocations which give rise to dislocations threading through the GaN into the active layers (e.g. InGaN quantum wells) of the devices. The key discovery for reducing the defect densities to tolerable levels was the use of nucleation layers at the interface with the sapphire [1.83] but densities of $\approx 10^9 \text{ cm}^{-2}$ remain typical. More recently epitaxial lateral overgrowth (ELOG) techniques have allowed the dislocation densities to be reduced to $\approx 10^6 \text{ cm}^{-2}$ in local regions [1.84]. However, perhaps the most interesting aspect of GaN-based optoelectronic devices is that they emit light so efficiently in spite of dislocation density orders of magnitude greater than those tolerated in conventional semiconductors.

Even though InGaN based light emitters have been commercially available for several years, the precise mechanism of luminescence from the alloy is still not fully understood. Having so far discussed the evolution of semiconductors with the benefit of hindsight we

can now for a moment consider an unresolved issue which, no doubt, will be solved in the coming years. It is widely believed that the tolerance of InGaN optoelectronic devices to high densities of defects is caused by the presence of low-energy sites within the layers at which electrons and holes are localised. They are thus prevented from interacting with the dislocations at which they would recombine in a non-radiative manner. The origin of localisation remains a matter of debate. One popular explanation is that the InGaN alloy has a tendency for phase segregation [1.85] and indium-rich “clusters” form and cause the localisation. However, there is now evidence [1.86] that the results of some of the measurements used to detect the indium rich regions could be misleading so the clustering explanation is being re-assessed. InGaN remains a fascinating and mysterious alloy.

Solid-state lighting will be a huge market for III-nitride materials in the coming decades. LEDs are perfectly suited to coloured light applications: their monochromatic emission is very much more energy efficient than the doubly wasteful process of colour filtering power hungry filament white light bulbs. InGaN LEDs are now the device of choice for green traffic signals worldwide and offer significant environmental benefits in the process. In principle there is also the opportunity to create white light sources for the home which are more efficient than the tungsten filament light bulbs used today and a variety of promising schemes have been developed for converting the coloured output of III-nitride LEDs to white sources. These include the use of three colour (red, green and blue) structures and blue InGaN or ultraviolet AlGaIn based LEDs coated with a range of phosphor materials to generate a useful white spectrum [1.65]. In particular ultraviolet LEDs coated with a three-way phosphor (red, green and blue) can produce high quality white light that mimics sunlight in its visible spectrum. The main disadvantages preventing the widespread use of LEDs in white lighting are their high cost and the relatively low output powers from single devices but these obstacles are rapidly being overcome.

Many other applications for the III-nitrides are being investigated including the use of (Al,Ga,In)N solar cells which could offer more efficient conversion of light into electric current than silicon based devices [1.87]; the possibility of lasers and optical switches operating at the crucial $1.55 \mu\text{m}$ wavelength based on intersubband (between the discrete quantised energy levels of the wells) transitions in AlGaIn/GaN quantum well structures; and the use of the compact InGaN LEDs to fluoresce labelled cancerous cells and aid detection of

affected areas. The wide band gap is also very attractive for many electronic device applications—particularly in high-temperature, high-power applications. Exploiting its high thermal conductivity and insensitivity to high operating temperatures, GaN-based HEMTs may extend the power of mobile phone base stations and it

has even been suggested that GaN devices could be used as an alternative source of ignition in car engines. There is also, of course, the possibility of monolithically integrating electronic and optoelectronic action onto a single chip. GaN-related materials should prove to have a huge impact on the technology of the coming decades.

1.4 From Faraday to Today

So, we have come 170 years from Faraday's nineteenth century observation of semiconductivity to a world dominated by electronic materials and devices. The balance of power between the different semiconductor families is an unstable and unpredictable one. For example if inexpensive, high quality, low defect density GaN substrates can be produced this will revolutionise the applications of GaN-based materials in both optoelectronics and electronics. The only inevitable fact is that the electronics revolution will continue to be crucially dependent on electronic materials understanding and improvement. And while reading the more focussed chapters in this

book and concentrating on the very important minutiae of a particular field, it can be a good idea to remember the bigger picture and the fact that electronic materials are remarkable!

Cambridge, October 2003

2. Electrical Conduction in Metals and Semiconductors

Electrical transport through materials is a large and complex field, and in this chapter we cover only a few aspects that are relevant to practical applications. We start with a review of the semi-classical approach that leads to the concepts of drift velocity, mobility and conductivity, from which Matthiessen's Rule is derived. A more general approach based on the Boltzmann transport equation is also discussed. We review the conductivity of metals and include a useful collection of experimental data. The conductivity of nonuniform materials such as alloys, polycrystalline materials, composites and thin films is discussed in the context of Nordheim's rule for alloys, effective medium theories for inhomogeneous materials, and theories of scattering for thin films. We also discuss some interesting aspects of conduction in the presence of a magnetic field (the Hall effect). We present a simplified analysis of charge transport in semiconductors in a high electric field, including a modern avalanche theory (the theory of "lucky" drift). The properties of low-dimensional systems are briefly reviewed, including the quantum Hall effect.

A good understanding of charge carrier transport and electrical conduction is essential for selecting or developing electronic materials for device applications. Of particular importance are the drift mobility of charge carriers in semiconductors and the conductivity of conductors and insulators. Carrier transport is a broad field that encompasses both traditional 'bulk' processes and, increasingly, transport in low dimensional or quantized structures. In other chapters of this handbook, Baranovskii describes hopping transport in low mobility solids such as insulators, Morigaki deals with the electrical properties of amorphous semiconductors and Gould discusses in detail conduction in thin films. In this chap-

ter, we outline a semi-quantitative theory of charge transport suitable for a wide range of solids of use to materials researchers and engineers. We introduce theories of "bulk" transport followed by processes pertinent to ultra-fast transport and quantized transport in lower dimensional systems. The latter covers such phenomena as the Quantum Hall Effect, and Quantized Conductance and Ballistic Transport in Quantum Wires that has potential use in new kinds of devices. There are many more rigorous treatments of charge transport; those by *Rossiter* [2.1] and *Dugdale* [2.2] on metals, and *Nag* [2.3] and *Blatt* [2.4] on semiconductors are highly recommended.

2.1 Fundamentals: Drift Velocity, Mobility and Conductivity

Basic to the theory of the electronic structure of solids are the solutions to the quantum mechanical problem of an electron in a periodic potential known as Bloch waves. These wavefunctions are traveling waves and provide the physical basis for conduction. In the semi-classical approach to conduction in materials, an electron wavepacket made up of a superposition of Bloch waves can in principle travel unheaded in an ideal crystal. No crystal is ideal, however, and the imperfections cause scattering of the wavepacket. Since the interaction of the electron with the potential of the ions is incorporated in the Bloch waves, one can concentrate on the relatively rare scattering events which greatly simplifies the theory. The motion of the electrons between scattering events is essentially free (with certain provisos such as no interband transitions) subject only to external forces, usually applied electric or magnetic fields. A theory can then be developed that relates macroscopic and measurable quantities such as conductivity or mobility to the microscopic scattering processes. Principle in such a theory is the concept of *mean free time* τ which is the average time between scattering events. τ is also known as the *conductivity relaxation time* because it represents the time scale for the momentum gained from an external field to relax. Equivalently, $1/\tau$ is the average probability per unit time that an electron is scattered.

There are two important velocity quantities that must be distinguished. The first is the *mean speed* u or *thermal velocity* v_{th} which as the name implies is the average speed of the electrons. u is quite large being on the order of $\sqrt{3k_B T/m_e^*} \approx 10^5$ m/s for electrons in a nondegenerate semiconductor and $\sqrt{2E_F/m_e^*} \approx 10^6$ m/s for electrons in a metal, where k_B is Boltzmann's constant, T is the temperature, E_F is the Fermi energy of the metal, and m_e^* is the electron effective mass. The distance an electron travels between scattering events is called the free path. It is straightforward to show that the average or *mean free path* for an electron is simply $\ell = u\tau$. The second velocity is the mean or *drift velocity* \mathbf{v}_d (variables in boldface are vectors) which is simply the vector average over the velocities of all N electrons,

$$\mathbf{v}_d = \frac{1}{N} \sum_{i=1}^N \mathbf{v}_i. \quad (2.1)$$

With no external forces applied to the solid, the electron motion is random and thus the drift velocity is zero. When subject to external forces like an electric field, the electrons acquire a net drift velocity. Normally, the

magnitude of the drift velocity is much smaller than u so that the mean speed of the electron is not affected to any practical extent by the external forces. An exception is charge transport in semiconductors in high electric fields, where $|\mathbf{v}_d|$ becomes comparable to u .

The drift velocity gives rise to an electric current. If the density of electrons is n then the current density \mathbf{J}_e is

$$\mathbf{J}_e = -en\mathbf{v}_d \quad (2.2)$$

where e is the fundamental unit of electric charge. For the important case of an applied electric field \mathbf{E} , the solutions of the semi-classical equations give a drift velocity that is proportional to \mathbf{E} . The proportionality constant is the *drift mobility* μ_e

$$\mathbf{v}_d = -\mu_e \mathbf{E}. \quad (2.3)$$

The drift mobility might be a constant or it might depend on the applied field (usually only if the field is large). Ohm's Law defines the conductivity σ of a material $\mathbf{J} = \sigma \mathbf{E}$ resulting in a simple relation to the drift mobility

$$\sigma = en\mu_e. \quad (2.4)$$

Any further progress requires some physical theory of scattering. A useful model results from the simple assumption that the scattering randomizes the electron's velocity (taking into proper account the distribution of electrons and the Pauli Exclusion Principle). The equation of motion for the drift velocity then reduces to a simple form

$$\frac{d\mathbf{v}_d}{dt} = \frac{\mathbf{F}(t)}{m_e^*} - \frac{\mathbf{v}_d}{\tau}, \quad (2.5)$$

where $\mathbf{F}(t)$ is the sum of all external forces acting on the electrons. The effect of the scattering is to introduce a frictional term into what otherwise would be just Newton's Law. Solutions of (2.5) depend on $\mathbf{F}(t)$. In the simplest case of a constant applied electric field, the steady-state solution is trivial,

$$\mathbf{v}_d = \frac{-e\mathbf{E}\tau}{m_e^*}. \quad (2.6)$$

The conductivity and drift mobility can now be related to the scattering time [2.5],

$$\mu_e = e\tau/m_e^* \quad \text{and} \quad \sigma = ne^2\tau/m_e^*. \quad (2.7)$$

More sophisticated scattering models lead to more accurate but more complicated solutions.

Fig. 2.1 Scattering of an electron from a scattering center. The electron travels a mean distance $\ell = u\tau$ between collisions

The simple expression (2.7) can be used to explain qualitative features of conduction in materials once a physical origin for the scattering is supplied. For any scattering site, the effective area is the *scattering cross-section* S as depicted in Fig. 2.1. The scattering cross section is related to the mean free path since the volume $S\ell$ must contain one scattering center. If there are N_S scattering centers per unit volume then

$$\ell = \frac{1}{SN_S}, \quad (2.8)$$

or, rewriting in terms of τ ,

$$\tau = \frac{1}{SN_S u}. \quad (2.9)$$

Once the cross-section for each physically relevant scattering mechanism is known then the effect on the scattering time and conductivity is readily calculated.

An overly restrictive assumption in the above analysis is that the electron's velocity is completely randomized every time it is scattered. On the other hand, suppose that ν collisions are required to completely destroy the directional velocity information. That is only after an average of ν collisions do all traces of correlation between the initial and the final velocities disappear. The *effective* mean free path ℓ_{eff} traversed by the electron until its velocity is randomized will now be larger than ℓ ; to first order $\ell_{\text{eff}} = \nu\ell$. ℓ_{eff} is termed the *effective* or the *conduction mean free path*. The corresponding

Fig. 2.2 An electron moving in the x-direction becomes scattered through an angle θ with respect to the original direction

effective scattering cross section is

$$S_{\text{eff}} = \frac{1}{N_S \ell_{\text{eff}}}. \quad (2.10)$$

The expressions for mobility and conductivity become

$$\mu = \frac{e\nu\tau}{m_e^*} = \frac{e\nu\ell}{m_e^* u} = \frac{e\ell_{\text{eff}}}{m_e^* u} = \frac{e}{m_e^* N_S S_{\text{eff}}} \quad (2.11)$$

and

$$\sigma = \frac{e^2 \nu \tau}{m_e^*} = \frac{e^2 n \nu \ell}{m_e^* u} = \frac{e^2 n \ell_{\text{eff}}}{m_e^* u} = \frac{e^2 n}{m_e^* N_S S_{\text{eff}}}. \quad (2.12)$$

Suppose that in a collision the electron is scattered at an angle θ to its original direction of travel as shown in Fig. 2.2. It is convenient to introduce a quantity $S_\theta(\theta)$, called the *differential scattering cross section*, defined so that $2\pi \sin \theta S_\theta d\theta$ represents the probability of scattering at an angle between θ and $\theta + d\theta$ with respect to the original direction. If the magnitude of the velocity is not changed then the fractional change in component of the velocity along the original direction is $1 - \cos \theta$. The average number of collisions ν required to randomize the velocity is then

$$\nu = \frac{1}{\langle 1 - \cos \theta \rangle}, \quad (2.13)$$

where the average is given by

$$\langle 1 - \cos \theta \rangle = \frac{\int_0^\pi (1 - \cos \theta) S_\theta(\theta) \sin \theta d\theta}{\int_0^\pi S_\theta(\theta) \sin \theta d\theta}. \quad (2.14)$$

The effective cross sectional area S_{eff} is then

$$S_{\text{eff}} = 2\pi \int_{\theta_m}^\pi (1 - \cos \theta) S_\theta(\theta) \sin \theta d\theta. \quad (2.15)$$

As an example, consider conduction electrons scattering from charged impurities in a nondegenerate semiconductor where small angle deviations predominate. The differential cross section for coulombic scattering from a charged impurity center with charge $+Ze$ is

$$S_{\theta}(\theta) = \frac{16k^2}{u^4} \times \frac{1}{\theta^4}; \quad k = \frac{Ze^2}{4\pi\epsilon m_e^*}, \quad (2.16)$$

where $k = Ze^2/4\pi\epsilon_0\epsilon_r m_e^*$ and ϵ_r is the relative permittivity of the semiconductor. Let r_m be the maximum effective radius of action for the impurity at which the minimum scattering angle occurs θ_m . Then the integral in (2.15) evaluates to

$$S_{\text{eff}} = \frac{2\pi k^2}{u^4} \ln \left(1 + \frac{r_m^2 u^4}{k^2} \right). \quad (2.17)$$

In a nondegenerate semiconductor, the equipartition theorem links velocity to temperature, $m_e^* u^2/2 = 3kT/2$, so

that $u \propto T^{1/2}$. Thus,

$$S_{\text{eff}} = \frac{A}{T^2} \ln(1 + BT^2), \quad (2.18)$$

where A and B are constants. The drift mobility due to scattering from ionized impurities becomes

$$\begin{aligned} \mu_I &= \frac{e}{m_e^* u S_{\text{eff}} N_I} \propto \frac{1}{T^{1/2}} \frac{T^2}{A \ln(1 + BT^2)} \frac{1}{N_I} \\ &\approx \frac{CT^{3/2}}{N_I}, \end{aligned} \quad (2.19)$$

where N_I is the density of ionized impurities and C is a new constant. At low temperatures where lattice scattering is insignificant, we expect $\mu_I \propto T^{3/2}/N_I$ for nondegenerate semiconductors.

The above semiquantitative description is sufficient to understand the basic principles of conduction. A more rigorous approach involves solving the Boltzmann charge transport equation and is addressed in Sect. 2.6.

2.2 Matthiessen's Rule

In general, the conduction electron whether in a metal or in a semiconductor can be scattered by a number of mechanisms, such as lattice vibrations, impurities, lattice defects such as dislocations, grain boundaries, vacancies, surfaces, or any other deviation from a perfectly periodic lattice. All these scattering processes increase the overall resistivity of the substance by reducing the mean scattering time. The relation between the types of scattering and the total scattering time can be obtained by considering scattering from lattice vibrations and im-

purities as shown in Figure 3.1. We define two mean free times τ_L and τ_I : τ_L is the mean free time considering only scattering from lattice vibrations (phonons) and τ_I is the mean free time considering only collisions with impurities. In a small unit of time dt , the total probability of scattering (dt/τ) is simply the sum of the probability for phonon scattering (dt/τ_L) and the probability for impurity scattering (dt/τ_I), and thus

$$\frac{1}{\tau} = \frac{1}{\tau_L} + \frac{1}{\tau_I}. \quad (2.20)$$

We have assumed that neither τ_L nor τ_I is affected by the presence of the other scattering mechanism, that is each type of scattering is independent. The above expression can be generalized to include all types of independent scattering yielding

$$\frac{1}{\tau} = \sum_i \frac{1}{\tau_i}, \quad (2.21)$$

where τ_i is the mean scattering time considering the i th scattering process alone. Since the drift mobility is proportional to τ , (2.21) can be written in terms of the drift mobilities determined by the various scattering mechanisms. In other words,

$$\frac{1}{\mu_d} = \sum_i \frac{1}{\mu_i} \quad (2.22)$$

Fig. 2.3 Scattering from lattice vibrations alone with a mean scattering time τ_L , and from impurities alone with a mean scattering time τ_I

where μ_i is the drift mobility limited just by the i th scattering process. Finally, since the resistivity is inversely proportional to the drift mobility, the relation for resistivity is

$$\rho = \sum_i \rho_i \quad (2.23)$$

where ρ_i is the resistivity of the material if only the i th scattering process were active. Equation (2.23) is known as Matthiessen's rule. For nearly perfect, pure

crystals the resistivity is dominated by phonon scattering ρ_T . If impurities or defects are present, however, there are an additional resistivities ρ_I from the scattering off the impurities and ρ_D from defect scattering, and $\rho = \rho_T + \rho_I + \rho_D$.

Matthiessen's rule is indispensable for predicting the resistivities of many types of conductors. In some cases like thin films, the rule is obeyed only approximately, but it is nonetheless still useful for an initial (often quite good) estimate.

2.3 Resistivity of Metals

2.3.1 General Characteristics

The effective resistivity of a metal, by virtue of Matthiessen's rule, is normally written as

$$\rho = \rho_T + \rho_R, \quad (2.24)$$

where ρ_R is called the *residual resistivity* and is due to the scattering of electrons by impurities, dislocations, interstitial atoms, vacancies, grain boundaries and so on. The residual resistivity shows very little temperature dependence whereas ρ_T is nearly linear in absolute temperature. ρ_T will be the main resistivity term for many good-quality, pure, crystalline metals. In classical terms, we can take the thermal vibrations of a lattice atom with mass M as having a mean kinetic energy KE of $(1/2)Ma^2\omega^2$, where a and ω are the amplitude and frequency of the vibrations. This mean KE must be of the order of kT so that the amplitude $a \propto T^{1/2}$. Thus the electron scattering cross section $S = \pi a^2 \propto T$. Since the mean speed of conduction electron in a metal is the Fermi speed and is temperature independent, $\mu \propto \tau \propto 1/S \propto T^{-1}$, and hence the resistivity $\rho \propto T$. Most nonmagnetic pure metals obey this relationship except at very low temperatures. Figure 2.4 shows the resistivity of Cu as a function of temperature where above ≈ 100 K, $\rho \propto T$.

Frequently, the resistivity vs. temperature behavior of pure metals can be empirically represented by a power law of the form,

$$\rho = \rho_0 \left(\frac{T}{T_0} \right)^n, \quad (2.25)$$

where ρ_0 is the resistivity at the reference temperature, T_0 , and n is a characteristic index that best fits the data. For the nonmagnetic metals, n is close to unity whereas it is close to 2 for the magnetic metals Fe and Ni [2.5]. Figure 2.5 shows ρ vs. T for various

metals. Table 2.1 summarizes the values ρ_0 and n for various metals.

As apparent from Fig. 2.4, below ≈ 100 K, the $\rho \propto T$ behavior fails, and $\rho \propto T^5$. The reason is that, as the temperature is lowered, the scattering by phonons becomes less efficient, and it takes many more collisions to fully randomize the initial velocity of the electron. The mean number of collisions ν required to randomize the velocity scales with T^{-2} [2.5], and at low temperatures,

Fig. 2.4 The resistivity of copper from low to high temperatures (near its melting temperature, 1358 K) on a log–log plot. Above about 100 K, $\rho \propto T$, whereas at low temperatures, $\rho \propto T^5$, and at the lowest temperatures ρ approaches the residual resistivity ρ_R . The inset shows the ρ vs. T behavior below 100 K on a linear plot. (ρ_R is too small to see on this scale.) After [2.5]

Fig. 2.5 The resistivities of various metals as a function of temperature above 0°C. Tin melts at 505 K, whereas nickel and iron go through a magnetic-to-nonmagnetic (Curie) transformation at about 627 K and 1043 K, respectively. The theoretical behavior ($\rho \propto T$) is shown for reference. After [2.5]

the concentration n_{phonon} of phonons increases as T^3 . Thus,

$$\sigma \propto v\tau \propto \frac{v}{n_{\text{phonon}}} \propto \frac{T^{-2}}{T^3} \propto T^{-5} \quad (2.26)$$

which explains the low-temperature $\rho - T$ behavior in Fig. 2.4. The low temperature $\rho \propto T^5$ and high temperature $\rho \propto T$ regimes are roughly separated by the *Debye temperature* T_D . For $T > T_D$ we expect $\rho \propto T$, and for $T < T_D$ we expect $\rho \propto T^5$.

In the case of metals with impurities and for alloys, we need to include the ρ_R contribution to the overall resistivity. For $T > T_D$, the overall resistivity is

$$\rho \approx AT + \rho_R, \quad (2.27)$$

where A is a constant, and the AT term in (2.27) arises from scattering from lattice vibrations. Normally, ρ_R has very little temperature dependence, and hence very roughly ρ vs. T curves shift to higher values as ρ_R is increased due to the addition of impurities, alloying or cold working the sample (mechanical deformation that generates dislocations) as illustrated for Cu–Ni alloys in Fig. 2.6.

Resistivity vs. temperature behavior of nearly all metals is characterized by the *temperature coefficient of resistivity* (TCR) α_0 which is defined as the fractional change in the resistivity per unit temperature increase at the reference temperature T_0 , i. e.

$$\alpha_0 = \frac{1}{\rho_0} \left(\frac{d\rho}{dT} \right)_{T=T_0}, \quad (2.28)$$

where ρ_0 is the resistivity at the reference temperature T_0 , usually at 273 K (0°C) or 293 K (20°C), $d\rho = \rho - \rho_0$ is the change in the resistivity due to a small increase, $dT = T - T_0$, in temperature. Assuming that α_0 is temperature independent over a small range from T_0 to T , we can integrate (2.28), which leads to the well known equation,

$$\rho = \rho_0[1 + \alpha_0(T - T_0)]. \quad (2.29)$$

Equation (2.29) is actually only valid when α_0 is *constant* over the temperature range of interest which requires (2.27) to hold. Over a limited temperature range this will usually be the case. Although it is not obvious from (2.28), we should, nonetheless, note that α_0 depends on the reference temperature, T_0 by virtue of ρ_0 depending on T_0 .

It is instructive to mention that if $\rho \approx AT$ as we expect for an ideal pure metal, then $\alpha_0 = T_0^{-1}$. If we take the reference temperature T_0 as 273 K (0°C), then α_0 should ideally be $1/(273 \text{ K})$ or $3.66 \times 10^{-3} \text{ K}^{-1}$. Examination of α_0 for various metals shows that $\rho \propto T$ is not a bad approximation for some of the familiar

Fig. 2.6 Resistivities of annealed and cold-worked (deformed) copper containing various amounts of Ni (given in atomic percentages) versus temperature

Table 2.1 Resistivities at 293 K (20 °C) ρ_0 and thermal coefficients of resistivity α_0 at 0–100 °C for various metals. The resistivity index n in $\rho = \rho_0(T/T_0)^n$ is also shown. Data was compiled from [2.6, 7]

pure metals used as conductors, e.g. Cu, Al, Au, but fails badly for others, such as indium, antimony

and, in particular, the magnetic metals, e.g. iron and nickel.

Frequently we are given α_0 at a temperature T_0 , and we wish to use some other reference temperature, say T_0' , that is, we wish to use ρ_0' and α_0' for ρ_0 and α_0 respectively in (2.29) by changing the reference from T_0 to T_0' . Then we can find α_1 from α_0 ,

$$\alpha_0' = \frac{\alpha_0}{1 + \alpha_0(T_0' - T_0)}$$

and $\rho = \rho_0' [1 + \alpha_0'(T - T_0')] . \quad (2.30)$

For example, for Cu $\alpha_0 = 4.31 \times 10^{-3} \text{ K}^{-1}$ at $T_0 = 0^\circ\text{C}$, but it is $\alpha_0 = 3.96 \times 10^{-3} \text{ K}^{-1}$ at $T_0 = 20^\circ\text{C}$. Table 2.1 summarizes α_0 for various metals.

2.3.2 Fermi Electrons

The electrical properties of metals depend on the behavior of the electrons at the Fermi surface. The electron states at energies more than a few kT below E_F are almost fully occupied. The Pauli exclusion principle requires that an electron can only be scattered into an empty state, and thus scattering of deep electrons is highly suppressed by the scarcity of empty states (scattering where the energy changes by more than a few kT is unlikely). Only the electrons near E_F undergo scattering. Likewise, under the action of an external field, only the electron occupation near E_F is altered. As a result, the density of states (DOS) near the Fermi level is most important for the metal electrical properties, and only those electrons in a small range ΔE around E_F actually contribute to electrical conduction. The density of these electrons is approximately $g(E_F)\Delta E$ where $g(E_F)$ is the DOS at the Fermi energy. From simple arguments, the overall conductivity can be shown to be [2.5]

$$\sigma = \frac{1}{3} e^2 v_F^2 \tau g(E_F) , \quad (2.31)$$

where v_F is the Fermi speed and τ is the scattering time of these Fermi electrons. According to (2.31), what is important is the density of states at the Fermi energy, $g(E_F)$. For example, Cu and Mg are metals with valencies I and II. Classically, Cu and Mg atoms each contribute 1 and 2 conduction electrons respectively into the crystal. Thus, we would expect Mg to have higher conductivity. However, the Fermi level in Mg is where the top tail of the 3p-band overlaps the bottom tail of the 3s band where the density of states is small. In Cu, on the other hand, E_F is nearly in the middle of the 4s band where the density of states is high. Thus, Mg has a lower conductivity than Cu.

Fig. 2.7a,b Simplified energy band diagrams around E_F for copper (a) and nickel (b)

The scattering time τ in (2.31) assumes that the scattered electrons at E_F remain in the same energy band as,

for example, in Cu, whose simplified energy band diagram around E_F is shown in Fig. 2.7a. In certain metals, there are two different energy bands that overlap at E_F . For example, in Ni, 3d and 4s bands overlap at E_F as shown in Fig. 2.7b. An electron can be scattered from the 4s to the 3d band and vice versa. Electrons in the 3d band have very low drift mobilities and effectively do not contribute to conduction so that only $g(E_F)$ of the 4s band operates in (2.31). Since 4s to 3d band is an additional scattering mechanism, by virtue of Matthiessen's rule, the effective scattering time τ for the 4s band electrons is shortened and hence σ from (2.31) is smaller. Thus, Ni has poorer conductivity than Cu.

Equation (2.31) does not assume a particular density of states model. If we now apply the *free electron model* for $g(E_F)$, and also relate E_F to the total number of conduction electrons per unit volume n , we would find that the conductivity is the same as that in the Drude model, that is

$$\sigma = \frac{e^2 n \tau}{m_e} . \quad (2.32)$$

2.4 Solid Solutions and Nordheim's Rule

In an *isomorphous alloy* of two metals, i.e. a binary alloy which forms a binary *substitutional solid solution*, an additional mechanism of scattering appears, the *scattering off solute phase atoms*. This scattering contributes to lattice scattering, and therefore increases the overall resistivity. An important semi-empirical equation which can be used to predict the resistivity of an alloy is Nordheim's rule. It relates the impurity part of the resistivity ρ_I to the atomic fraction X of solute atoms in a solid solution via

$$\rho_I = CX(1 - X) , \quad (2.33)$$

where the constant C is termed the Nordheim coefficient and represents the effectiveness of the solute atom in increasing the resistivity. Nordheim's rule was originally derived for crystals. Combining Nordheim's rule with Matthiessen's rule (2.23), the resistivity of an alloy of composition X should follow

$$\rho = \rho_{\text{matrix}} + CX(1 - X) , \quad (2.34)$$

where ρ_{matrix} is the resistivity of the matrix due to scattering from thermal vibrations and from other defects, in the absence of alloying elements.

Nordheim's rule assumes that the solid solution has the solute atoms randomly distributed in the lattice. For sufficiently small amounts of impurity, experiments show that the increase in the resistivity ρ_I is nearly always simply proportional to the impurity concentration X , that is, $\rho_I \propto X$. For dilute solutions, Nordheim's rule predicts the same linear behavior, that is, $\rho_I = CX$ for $X \ll 1$.

Originally the theoretical model for ρ_I was developed by Nordheim [2.8] by assuming that the solute atoms simply perturb the periodic potential and thereby increase the probability of scattering. Quantum mechanical calculations for electron scattering within a single band, such as the *s*-band, at E_F show that

$$\rho_I \propto g(E_F) V_{\text{scatter}}^2 X(1 - X) , \quad (2.35)$$

where $g(E_F)$ is the DOS at E_F , and V_{scatter} is matrix element for scattering from one wavefunction to another at the Fermi surface in the same band, which for an *s*-band is

$$V_{\text{scatter}} = \langle \psi_s^* | \Delta V | \psi_s \rangle , \quad (2.36)$$

Table 2.2 Nordheim coefficients (at 20 °C) for dilute alloys obtained from $\rho_i = CX$ and $X < 1$ at.%. Note: For many isomorphous alloys, C may be different at higher concentrations; that is, it may depend on the composition of the alloy [2.7, 9]. Maximum solubility data from [2.10]

Solute in solvent (element in matrix)	Nordheim coefficient (nΩ m)	Maximum solubility at 25 °C (at.%)
Au in Cu matrix	5500	100
Mn in Cu matrix	2900	24
Ni in Cu matrix	1250	100
Sn in Cu matrix	2900	0.6
Zn in Cu matrix	300	30
Cu in Au matrix	450	100
Mn in Au matrix	2410	25
Ni in Au matrix	790	100
Sn in Au matrix	3360	5
Zn in Au matrix	950	15

where ΔV is the difference between the potentials associated with solvent and solute atoms, and ψ_s is the wavefunction of an electron in the s-band at E_F . It is clear that C is only independent of X if $g(E_F)$ and V_{scatter} remain the same for various X which may not be true. For example, if the effective number of free electrons increases with X , E_F will be shifted higher, and C will not be constant.

Table 2.2 lists some typical Nordheim coefficients for various additions to copper and gold. The value of the Nordheim coefficient depends on the type of solute and the solvent. A solute atom that is drastically different in size to the solvent atom will result in a bigger increase in ρ_l and will therefore lead to a larger C . An important assumption in Nordheim's rule in (2.33) is that the alloying does not significantly vary the number of conduction electrons per atom in the alloy. Although this will be true for alloys with the same valency, that is, from the same column in the Periodic Table (e.g., Cu–Au, Ag–Au), it will not be true for alloys of different valency, such as Cu and Zn. In pure copper, there is just one conduction electron per atom, whereas each Zn atom can donate two conduction electrons. As the Zn content in brass is increased, more conduction electrons become available per atom. Consequently, the resistivity predicted by (2.34) at high Zn contents is greater than the actual value because C refers to dilute alloys. To get the correct resistivity from (2.34) we have to lower C , which is equivalent to using an *effective* Nordheim coefficient

Fig. 2.8 Electrical resistivity versus composition at room temperature in Cu–Au alloys. The quenched sample (dashed curve) is obtained by quenching the liquid, and it has the Cu and Au atoms randomly mixed. The resistivity obeys the Nordheim rule. On the other hand, when the quenched sample is annealed or the liquid slowly cooled (solid curve), certain compositions (Cu₃Au and CuAu) result in an ordered crystalline structure in which Cu and Au atoms are positioned in an ordered fashion in the crystal and the scattering effect is reduced

C_{eff} that decreases as the Zn content increases. In other cases, for example, in Cu–Ni alloys, we have to increase C at high Ni concentrations to account for additional electron scattering mechanisms that develop with Ni addition. Nonetheless, the Nordheim rule is still useful for predicting the resistivities of dilute alloys, particularly in the low-concentration region.

In some solid solutions, at some concentrations of certain binary alloys, such as 75% Cu–25% Au and 50% Cu–50% Au, the annealed solid has an orderly structure; that is, the Cu and Au atoms are not randomly mixed, but occupy regular sites. In fact, these compositions can be viewed as a pure compound – like the solids Cu₃Au and CuAu. The resistivities of Cu₃Au and CuAu will therefore be less than the same composition random alloy that has been quenched from the melt. As a consequence, the resistivity ρ versus composition X curve does not follow the dashed parabolic curve throughout; rather, it exhibits sharp falls at these special compositions, as illustrated Fig. 2.8. The *effective media approximation* may be used as an effective tool to estimate the resistivities of inhomogeneous media.

2.5 Carrier Scattering in Semiconductors

At low electric fields, ionized impurity scattering and phonon scattering predominate. Other types of scattering include carrier-carrier scattering, inter-valley scattering, and neutral impurity scattering; these may generally be ignored to a first approximation.

For phonon scattering, both *polar* and *non-polar phonon scattering* should be considered. In polar scattering, short wavelength oscillations of atoms on different sub-lattices vibrating out of phase produce an effective dipole moment proportional to the bond polarity. Since such vibrational modes are optically active (since this dipole moment can interact with an incident electromagnetic field), this type of lattice scattering is usually referred to as *polar optical phonon scattering*. Since a sub-lattice is necessary for optical modes, this scattering mechanism is not present in elemental semiconductors such as Si, Ge, or diamond.

Non-polar phonon scattering comes from long wavelength oscillations in the crystal, involving small displacements of tens to thousands of atoms. The wavelength depends on the material and its elastic properties. Such modes are very similar to sound vibrations and are thus referred to as acoustic modes. The associated atomic displacements correspond to an effective built-in strain, with local change in the lattice potential, causing carrier scattering known as *deformation potential acoustic phonon scattering*. Since the change in potential is relatively small, the scattering efficiency is relatively low as compared with polar optical phonon scattering.

Each scattering process contributes to the drift mobility according to *Matthiessen's rule*

$$\frac{1}{\mu_e} = \sum_i \frac{1}{\mu_i} \quad (2.37)$$

as discussed in Sect. 2.3 above. Figure 2.9 shows the contributions of each scattering process for n-type ZnSe – a material used in optoelectronic devices. At room temperature, polar optical phonon scattering and ionized impurity scattering dominate. These processes depend on the carrier concentration. The curve for ionized impurity scattering decreases markedly with increasing carrier concentration owing to the increasing concentration of ionized donors that supply these carriers. The ionized impurity scattering mobility is roughly inversely proportional to the concentration of ionized impurities. However, as the carrier concentration increases, as in a degenerate semiconductor, the average energy per carrier also increases (i. e., carriers move faster on average) and thus carriers are less susceptible to being scattered from the

Fig. 2.9 Dependence of electron mobility on carrier concentration for ZnSe at 77 K [2.11]

Fig. 2.10 Dependence of electron mobility on temperature and doping for ZnSe [2.11]

ionized impurity centers. In contrast, the polar phonon scattering rate is determined by the number of participating phonons which depends on the thermal energy available to create a given quantized vibrational mode.

The temperature dependence of the mobility may be estimated by considering the effect of temperature on ionized impurity and phonon scattering and combining these mechanisms using Matthiessen's rule. Phonon scattering increases strongly with increasing temperature T due to the increase in the number of phonons resulting in a $T^{-3/2}$ dependence for the polar phonon mobility. For ionized impurity scattering, increasing the temperature increases the average carrier velocity and hence increases the carrier mobility for a set concentration of ionized impurities. Once a temperature is reached

such that impurity ionization is complete, the ionized impurity based carrier mobility can be shown to increase with temperature T as approximately, $T^{+3/2}$. At low temperatures, the mobility is basically determined by ionized impurity scattering and at high temperatures by phonon scattering leading to a peaked curve. Invoking the previous discussions for the dependence of the total mobility on carrier concentration, it is clear that the peak mobility will depend on the doping level, and the peak location will shift to higher temperatures with increased doping as shown in Fig. 2.10.

2.6 The Boltzmann Transport Equation

A more rigorous treatment of charge transport requires a discussion of the *Boltzmann Transport Equation*. The electronic system is described by a distribution function $f(\mathbf{k}, \mathbf{r}, t)$ defined in such a way that the number of electrons in a six-dimensional volume element $d^3\mathbf{k}d^3\mathbf{r}$ at time t is given by $\frac{1}{4}\pi^{-3}f(\mathbf{k}, \mathbf{r}, t)d^3\mathbf{k}d^3\mathbf{r}$. In equilibrium, $f(\mathbf{k}, \mathbf{r}, t)$ depends only on energy and reduces to the Fermi distribution f_0 where the probability of occupation of states with momenta $+\mathbf{k}$ equals that for states with $-\mathbf{k}$, and $f_0(\mathbf{k})$ is symmetrical about $\mathbf{k} = 0$, giving no net charge transport. If an external field acts on the system (i.e., non-equilibrium), the occupation function $f(\mathbf{k})$ will become asymmetric in \mathbf{k} -space. If this non-equilibrium distribution function $f(\mathbf{k})$ is completely specified and appropriate boundary conditions supplied, the electronic transport properties can be completely determined by solving the *steady state Boltzmann transport equation* [2.12]

$$\mathbf{v} \cdot \nabla_{\mathbf{r}} f + \hbar \mathbf{k} \cdot \nabla_{\mathbf{k}} f = \left(\frac{\partial f}{\partial t} \right)_c \quad (2.38)$$

where,

1. $\mathbf{v} \cdot \nabla_{\mathbf{r}} f$ represents diffusion through a volume element $d^3\mathbf{r}$ about the point \mathbf{r} in phase space due to a gradient $\nabla_{\mathbf{r}} f$,
2. $\hbar \mathbf{k} \cdot \nabla_{\mathbf{k}} f$ represents drift through a volume element $d^3\mathbf{k}$ about the point \mathbf{k} in phase space due to a gradient $\nabla_{\mathbf{k}} f$ (for example, $\hbar \dot{\mathbf{k}} = e(\mathbf{E} + \frac{1}{c}\mathbf{v} \times \mathbf{B})$ in the presence of electric and magnetic fields)
3. $(\partial f / \partial t)_c$ is the collision term and accounts for the scattering of electrons from a point \mathbf{k} (for example, this may be due to lattice or ionized impurity scattering).

Equation (2.38) may be simplified by using the *relaxation time approximation*

$$\left(\frac{\partial f}{\partial t} \right)_c = \frac{\Delta f}{\tau} = -\frac{f - f_0}{\tau} \quad (2.39)$$

which is based on the assumption that for small changes in f carriers return to equilibrium in a characteristic time τ , dependent on the dominant scattering mechanisms. Further simplifications of (2.38) using (2.39) applicable for low electric fields lead to a simple equation connecting the mobility μ to the *average scattering time* $\langle \tau \rangle$

$$\mu \cong \frac{e\langle \tau \rangle}{m^*} \quad (2.40)$$

The details of calculations may be found in various advanced textbooks, for example *Bube* [2.13], *Blatt* [2.4]. The average scattering time may be calculated assuming a *Maxwell-Boltzmann* distribution function and a parabolic band

$$\langle \tau \rangle = \frac{2}{3k_B T} \frac{\int_0^\infty \tau(E) E^{3/2} e^{-E/k_B T} dE}{\int_0^\infty E^{1/2} e^{-E/k_B T} dE} \quad (2.41)$$

Quantum mechanical perturbation theory can be used to calculate the carrier scattering rate for different processes i , giving,

$$\tau_i(E) = aE^{-\alpha} \quad (2.42)$$

where a and α are constants and E is the electron energy. Substituting (2.42) into (2.41) gives

$$\langle \tau_i \rangle = \frac{4a\Gamma(5/2 - \alpha)}{3\pi^{1/2}(k_B T)^\alpha} \quad (2.43)$$

in terms of the *gamma function* Γ . Using this approach, the expressions for the mobility for the case

of lattice and impurity scattering may be easily found

$$\mu_L \propto \frac{4e}{m^* \sqrt{9\pi k_B}} T^{-\frac{3}{2}}, \quad (2.44)$$

$$\mu_I \propto \frac{8ek_B^{3/2} N_I}{m^* \sqrt{\pi}} T^{+\frac{3}{2}}, \quad (2.45)$$

where N_I is the concentration of ionized impurities.

2.7 Resistivity of Thin Polycrystalline Films

Two new dominant scattering mechanisms must be considered in polycrystalline thin films – *scattering by grain boundaries* and *scattering at the surface*. The scattering by grain boundaries is schematically shown in Fig. 2.11. As a first approximation, the conduction electron may be considered free within a grain, but becomes scattered at the grain boundary. Its mean free path ℓ_{grains} is therefore roughly equal to the average grain size d . If $\lambda = \ell_{\text{crystal}}$ is the mean free path of the conduction electrons in the single crystal, then according to Matthiessen's rule

$$\frac{1}{\ell} = \frac{1}{\ell_{\text{crystal}}} + \frac{1}{\ell_{\text{grains}}} = \frac{1}{\lambda} + \frac{1}{d}. \quad (2.46)$$

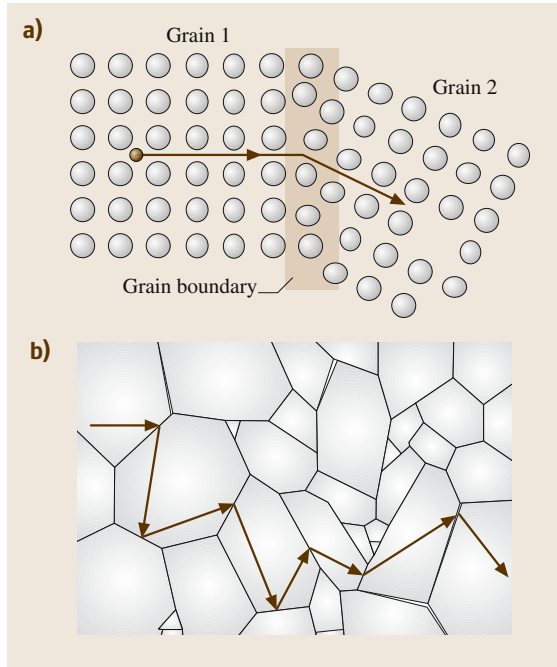

Fig. 2.11 (a) Grain boundaries cause electron scattering and therefore add to the resistivity according to Matthiessen's rule. (b) For a very grainy solid, the electron is scattered from grain boundary to grain boundary, and the mean free path is approximately equal to the mean grain diameter

The resistivity is inversely proportional to the mean free path which means the resistivity of the single crystal $\rho_{\text{crystal}} \propto 1/\lambda$ and resistivity of the polycrystalline sample $\rho \propto 1/\ell$. Thus,

$$\frac{\rho}{\rho_{\text{crystal}}} = 1 + \left(\frac{\lambda}{d} \right). \quad (2.47)$$

Figure 2.12 clearly demonstrates that even simple considerations agree well with experimental data. However, in a more rigorous theory we have to consider a number of effects. It may take more than one scattering at a grain boundary to totally randomize the velocity so that we need to calculate the effective mean free path that accounts for how many collisions are needed to randomize the velocity. There is a possibility that the electron may be totally reflected back at a grain boundary (bounce back). Let σ be the conductivity of the polycrystalline (grainy) material and σ_{crystal} be the conductivity of the bulk single crystal. Suppose that the probability of reflection at a grain boundary is R . If d is the average grain size (diameter) then the two conductivities may be related using the *Mayadas and Shatzkes*

Fig. 2.12 Resistivity of Cu polycrystalline film vs. reciprocal mean grain size (diameter), $1/d$. Film thickness $D = 250\text{--}900\text{ nm}$ does not affect the resistivity. The straight line $\rho = 17.8\text{ n}\Omega\text{ m} + (595\text{ n}\Omega\text{ nm})(1/d)$ [2.14]

formula [2.15]

$$\frac{\sigma}{\sigma_{\text{crystal}}} = 1 - \frac{3}{2}\beta + 3\beta^2 - 3\beta^3 \ln\left(1 + \frac{1}{\beta}\right)$$

where $\beta = \frac{\lambda}{d} \left(\frac{R}{1-R} \right)$, (2.48)

which in $0.1 < \beta < 10$, approximates to

$$\frac{\rho}{\rho_{\text{crystal}}} \approx 1 + 1.34\beta. \quad (2.49)$$

For copper typically R values are 0.24–0.40, and somewhat a smaller R for Al. Equation (2.49) for a Cu film with $R \approx 0.3$ predicts $\rho/\rho_{\text{crystal}} \approx 1.20$ for roughly $d \approx 3\lambda$ or a grain size $d \approx 120$ nm since in the bulk crystal $\lambda \approx 40$ nm. Tellier et al. [2.17] have given extensive discussions of grain boundary scattering limited resistivity of thin films.

Scattering from the film surfaces must also be included in any resistivity calculation. It is generally assumed that the scattering from a surface is partially *inelastic*, that is the electron loses some of the velocity gained from the field. The inelastic scattering is also called *nonspecular*. (If the electron is elastically reflected from the surface just like a rubber ball bouncing from a wall, then there is no increase in the resistivity.) If the parameter p is the fraction of surface collisions which are specular (elastic) and if the thickness of film D is greater than λ , and $\sigma_{\text{bulk}} = 1/\rho_{\text{bulk}}$, then in accordance with Fuchs-Sondheimer equation [2.18, 19] the conductivity σ of the film is

$$\frac{\sigma}{\sigma_{\text{bulk}}} = 1 - \frac{3\lambda}{8D}(1-p), \quad (\lambda/D > 1). \quad (2.50)$$

If D is much shorter than ℓ ,

$$\frac{\sigma}{\sigma_{\text{bulk}}} = \frac{3D}{4\lambda} \left[\ln\left(\frac{\lambda}{D}\right) + 0.423 \right] \times (1+2p), \quad (\lambda/D \ll 1). \quad (2.51)$$

For purely nonspecular (inelastic) scattering, an approximate estimate can be obtained from

$$\frac{\rho}{\rho_{\text{bulk}}} \approx 1 + \frac{3}{8} \left(\frac{\lambda}{D} \right). \quad (2.52)$$

Figure 2.13 shows the resistivity of thin polycrystalline Cu films as a function of film thickness. From (2.50), for sufficiently small thicknesses, ρ is inversely proportional to the thickness D , which is what is observed experimentally in Fig. 2.13. The saturation at higher thicknesses is mostly due to scattering on grain boundaries.

Fig. 2.13 Resistivity of Cu polycrystalline film versus film thickness D . The resistivity is mostly controlled by the surface scattering, and annealing does not significantly affect the resistivity while it reduces the crystallinity [2.16]

For elastic or specular scattering $p = 1$ and there is no change in the conductivity. The value of p depends on the film preparation method (e.g. sputtering, epitaxial growth etc.) and the substrate on which the film has been deposited. Table 2.3 summarizes the resistivities of thin Cu and Au gold films deposited by various preparation techniques. Notice the large difference between the Au films deposited on a noncrystalline glass substrate and on a crystalline mica substrate. Such differences between films are typically attributed to different values of p . The p -value can also change (increase) when the film is annealed. Obviously, the polycrystallinity of the film will also affect the resistivity as discussed above. Typically, most epitaxial thin films, unless very thin ($D \ll \ell$), deposited onto heated crystalline substrates exhibit highly specular scattering with $p = 0.9 - 1$.

It is generally very difficult to separate the effects of surface and grain boundary scattering in thin polycrystalline films; the contribution from grain boundary scattering is likely to exceed that from the surfaces. In any event, both contributions, by Matthiessen's general rule, increase the overall resistivity. Figure 2.12 shows an example in which the resistivity ρ_{film} of thin Cu polycrystalline films is due to grain boundary scattering, and thickness has no effect (D was 250 nm – 900 nm and much greater than λ). The resistivity ρ_{film} is plotted against the reciprocal mean grain size $1/d$, which then follows the expected linear behavior in (2.49). On the other hand, Fig. 2.13 shows the resistivity of Cu films as a function of film thickness D . In this case, annealing (heat treating) the films to reduce the polycrystallinity

Table 2.3 Resistivities of some thin Cu and Au films at room temperature. **PC**: Polycrystalline film; RT is room temperature; D = film thickness; d = average grain size. At RT for Cu, $\lambda = 38\text{--}40\text{ nm}$, and for Au $\lambda = 36\text{--}38\text{ nm}$. Data selectively combined from various sources, including [2.14, 16, 20–22].

Film	D (nm)	d (nm)	ρ (n Ω m)	Comment
Cu films (polycrystalline)				
Cu on TiN, W and TiW [2.14]	> 250	186	21	CVD (chemical vapor deposition). Substrate temperature 200 °C, ρ depends on d not $D = 250\text{--}900$ nm
		45	32	
Cu on 500 nm SiO ₂ [2.20]	20.5		35	Thermal evaporation, substrate at RT
	37		27	
Cu on Si (100) [2.16]	52		38	Sputtered Cu films. Annealing at 150 °C has no effect. $R \approx 0.40$ and $p \approx 0$
	100		22	
Cu on glass [2.21]	40		50	As deposited
	40		29	Annealed at 200 °C
	40		25	Annealed at 250 °C
				All thermally evaporated and PC
Au films				
Au epitaxial film on mica	30		25	Single crystal on mica. $p \approx 0.8$, specular scattering
Au PC film on mica	30		54	PC. Sputtered on mica. p is small
Au film on glass	30		70	PC. Evaporated onto glass. p is small, nonspecular scattering
Au on glass [2.22]	40		8.5	92
	40	3.8	189	

does not significantly affect the resistivity because ρ_{film} is controlled primarily by surface scattering, and is given

by (2.52). Gould in Chapt. 29 provides a more advanced treatment of conduction in thin films.

2.8 Inhomogeneous Media. Effective Media Approximation

The *effective media approximation* (**EMA**) attempts to estimate the properties of inhomogeneous mixture of two or more components using the known physical properties of each component. The general idea of any **EMA** is to substitute for the original inhomogeneous mixture some imaginary homogeneous substance – the *effective medium* (**EM**) – whose response to an external excitation is the same as that of the original mixture. The **EMA** is widely used for investigations of non-uniform objects in a variety of applications such as composite materials [2.23, 24], microcrystalline and amorphous semiconductors [2.25–28], light scattering [2.29], conductivity of dispersed ionic semiconductors [2.30] and many others.

Calculations of the conductivity and dielectric constant of two component mixtures are reviewed by Reynolds and Hough [2.31] and summarized by

Rossiter [2.1]. For such a mixture we assume that the two components α and β are randomly distributed in space with volume fractions of χ_α and $\chi_\beta = 1 - \chi_\alpha$. The dielectric properties are described by an *effective permittivity* ϵ_{eff} given by the ratio

$$\epsilon_{\text{eff}} = \langle D \rangle / \langle E \rangle , \tag{2.53}$$

where $\langle E \rangle$ is the average electric field and $\langle D \rangle$ is the average displacement field. The displacement field averaged over a large volume may be calculated from

$$\begin{aligned} \langle D \rangle &= \frac{1}{V} \int_V D dv = \frac{1}{V} \left(\int_{V_\alpha} D dv + \int_{V_\beta} D dv \right) \\ &= \chi_\alpha \langle D_\alpha \rangle + \chi_\beta \langle D_\beta \rangle , \end{aligned} \tag{2.54}$$

Table 2.4 Mixture rules for randomly oriented particles

Spheres	$\frac{\epsilon_{\text{eff}} - \epsilon_\beta}{3\epsilon_\beta} = \chi_\alpha \frac{\epsilon_\alpha - \epsilon_\beta}{\epsilon_\alpha + 2\epsilon_\beta}$	$\frac{1}{3}$	ϵ_2	[2.37]
Spheres	$\chi_\alpha \frac{\epsilon_\alpha - \epsilon_{\text{eff}}}{\epsilon_\alpha + 2\epsilon_{\text{eff}}} + \chi_\beta \frac{\epsilon_\beta - \epsilon_{\text{eff}}}{\epsilon_\beta + 2\epsilon_{\text{eff}}} = 0$	$\frac{1}{3}$	ϵ_{eff}	[2.38]
Spheres	$\frac{\epsilon_{\text{eff}} - \epsilon_\beta}{3\epsilon_{\text{eff}}} = \chi_\alpha \frac{\epsilon_\alpha - \epsilon_\beta}{\epsilon_\alpha + 2\epsilon_\beta}$	$\frac{1}{3}$	ϵ_{eff}	[2.39]
Spheroids	$\epsilon_{\text{eff}} = \epsilon_\beta + \frac{\chi_\alpha}{3(1 - \chi_\alpha)} \sum_{n=1}^3 \frac{\epsilon_\alpha - \epsilon_{\text{eff}}}{1 + A \left(\frac{\epsilon_\alpha}{\epsilon_{\text{eff}}} - 1 \right)}$	A	ϵ_2	[2.40]
Spheroids	$\epsilon_{\text{eff}} = \epsilon_\beta + \frac{\chi_\alpha}{3} \sum_{n=1}^3 \frac{\epsilon_\alpha - \epsilon_{\text{eff}}}{1 + A \left(\frac{\epsilon_\alpha}{\epsilon_{\text{eff}}} - 1 \right)}$	A	ϵ_{eff}	[2.41]
Lamellae	$\epsilon_{\text{eff}}^2 = \frac{2(\epsilon_\alpha \chi_\alpha - \epsilon_\beta \chi_\beta) - \epsilon_{\text{eff}}}{\frac{\epsilon_\alpha}{\chi_\alpha} + \frac{\epsilon_\beta}{\chi_\beta}}$	0	ϵ_{eff}	[2.38]
Rods	$5\epsilon_{\text{eff}}^3 + (5\epsilon'_p - 4\epsilon_p)\epsilon_{\text{eff}}^2 - (\chi_\alpha \epsilon_\alpha^2 + 4\epsilon_\alpha \epsilon_\beta + \chi_\beta \epsilon_\beta^2) - \epsilon_\alpha \epsilon_\beta \epsilon_p = 0$ where $\frac{1}{\epsilon'_p} = \frac{\chi_\alpha}{\epsilon_\beta} + \frac{\chi_\beta}{\epsilon_\alpha}$ and $\frac{1}{\epsilon_p} = \frac{\chi_\alpha}{\epsilon_\alpha} + \frac{\chi_\beta}{\epsilon_\beta}$	$\frac{1}{2}$	ϵ_{eff}	[2.42]

where $\langle D_\alpha \rangle$ and $\langle D_\beta \rangle$ are the average displacements fields inside regions of the respective components and V_α and V_β are their volumes. Likewise the electric field is given by

$$\langle E \rangle = \chi_\alpha \langle E_\alpha \rangle + \chi_\beta \langle E_\beta \rangle. \quad (2.55)$$

From (2.53) one gets

$$\epsilon_{\text{eff}} = \epsilon_\beta + (\epsilon_\alpha - \epsilon_\beta) \chi_\alpha f_\alpha \quad (2.56)$$

or

$$(\epsilon_{\text{eff}} - \epsilon_\alpha) \chi_\alpha f_\alpha + (\epsilon_{\text{eff}} - \epsilon_\beta) \chi_\beta f_\beta = 0 \quad (2.57)$$

where ϵ_α and ϵ_β are the permittivities of the components and $f_\alpha = \langle E_\alpha \rangle / \langle E \rangle$ and $f_\beta = \langle E_\beta \rangle / \langle E \rangle$ are so-called *field factors*. The choice between (2.56) and (2.57) depends on particle geometry. Equation (2.56) is better when the particles of component are dispersed in a continuous medium β . Equation (2.57) is preferred when the particle size of the two components is of the same order of magnitude.

The field factors can be calculated analytically only for phase regions with special specific geometries. The field factor for ellipsoids is given by (Stratton [2.43])

$$f_\alpha = \sum_{i=1}^3 \frac{\cos^2 \alpha_i}{1 + A_i \left(\frac{\epsilon_\alpha}{\epsilon^*} - 1 \right)} \quad (2.58)$$

where α_i are the angles between the ellipsoid axes and the applied field and A_i depends upon the axial ratios of the ellipsoids subject to the condition that

$$\sum_{i=1}^3 A_i = 1.$$

For a spheroid, $A_2 = A_3 = A$ and $A_1 = 1 - 2A$. For a random orientation of spheroids $\cos^2 \alpha_1 = \cos^2 \alpha_2 = \cos^2 \alpha_3 = \frac{1}{3}$. For the case of long particles with aligned axes $\cos^2 \alpha_1 = \cos^2 \alpha_2 = \frac{1}{2}$ and $\cos^2 \alpha_3 = 0$. The values of parameters entering (2.58) can be found in Table 2.4 which shows a set of *mixture rules*, i.e.

Lamellae with all axes aligned (current lines are parallel to lamellae planes)	$\varepsilon_{\text{eff}} = \varepsilon_\alpha \chi_\alpha + \varepsilon_\beta \chi_\beta$	0	ε_{eff}	1	0	[2.45, 46]
Spheroids with all axes aligned (current lines are parallel to one of the axes)	$\varepsilon_{\text{eff}} = \varepsilon_\beta + \frac{\chi_\alpha (\varepsilon_\alpha - \varepsilon_\beta)}{1 + A \left(\frac{\varepsilon_\alpha}{\varepsilon_\beta} - 1 \right)}$	A	ε_2	0	1	[2.47]
Spheroids with all axes aligned (current lines are parallel to one of the axes)	$\frac{\varepsilon_{\text{eff}}}{\varepsilon_\beta} = 1 + \frac{\chi_\alpha}{\left(\frac{\varepsilon_\alpha}{\varepsilon_\beta} - 1 \right)^{-1} + A \chi_\beta}$	A	ε_2	0	1	[2.48]

Table 2.6 Conductivity / resistivity mixture rules

Particle shape	Formula	Commentary
Lamellae with all axes aligned (current lines are perpendicular to lamellae planes)	$\rho_{\text{eff}} = \chi_\alpha \rho_\alpha + \chi_\beta \rho_\beta$	<i>Resistivity mixture rule:</i> ρ_α and ρ_β are the resistivities of two phases and ρ_{eff} is the effective resistivity of mixture
Lamellae with all axes aligned (current lines are parallel to lamellae planes)	$\sigma_{\text{eff}} = \chi_\alpha \sigma_\alpha + \chi_\beta \sigma_\beta$	<i>Conductivity mixture rule:</i> σ_α and σ_β are the conductivities of two phases and σ_{eff} is the effective conductivity of mixture
Small spheroids (α -phase) in medium (β -phase)	$\rho_{\text{eff}} = \rho_\beta \frac{(1 + \frac{1}{2} \chi_\alpha)}{(1 - \chi_\alpha)}$	$\rho_\alpha > 10 \rho_\beta$
Small spheroids (α -phase) in medium (β -phase)	$\rho_{\text{eff}} = \rho_\beta \frac{(1 - \chi_\alpha)}{(1 + 2 \chi_\alpha)}$	$\rho_\alpha < 0.1 \rho_\beta$

a set of formulae allowing one to calculate ε_{eff} for some specific cases (such as spheres, rods, lamellae, etc.). The presence of some degree of orientation somewhat simplifies the calculations as shown in the Table 2.5.

The same formulae can be used to calculate the conductivity of mixtures by substituting the appropriate conductivity σ for ε . For some special cases, the mixture rules of Table 2.5 lead to very simple formulae which allows one to calculate the conductivity of inhomogeneous alloys with those specific geometries. These *mixture rules* are summarized in Table 2.6.

The most general approach to calculating the effective dielectric permittivity comes from

$$\varepsilon_{\text{eff}} = \varepsilon_2 \left(1 - \chi_\alpha \int_0^1 \frac{G(L)}{t - L} dL \right) \quad (2.59)$$

where $t = \varepsilon_2 / (\varepsilon_2 - \varepsilon_1)$ and $G(L)$ is the *spectral function* which describes the geometry of particles. The advantage of the spectral representation is that it distinguishes between the influence of geometrical quantities and that of the dielectric properties of the components on the effective behavior of the sys-

Table 2.7 Mixture rules and corresponding spectral functions $G(L)$

Mixture rule by <i>Bruggemann</i> [2.38]: $\chi_\alpha \frac{\varepsilon_\alpha - \varepsilon_{\text{eff}}}{\varepsilon_\alpha + 2\varepsilon_{\text{eff}}} + \chi_\beta \frac{\varepsilon_\beta - \varepsilon_{\text{eff}}}{\varepsilon_\beta + 2\varepsilon_{\text{eff}}} = 0$	
$G(L) = \frac{3\chi_\alpha - 1}{2\chi_\alpha} \delta(L) \Theta(3\chi_\alpha - 1) + \frac{3}{4\pi\chi_\alpha L} \sqrt{(L - L^-)(L^+ - L)} \Theta(L - L^-) \Theta(L^+ - L)$	
where $L^{+/-} = \frac{1}{3} \left(1 + \chi_\alpha \pm 2\sqrt{2\chi_\alpha - 2\chi_\alpha^2} \right)$	
Mixture rule by <i>Maxwell-Garnett</i> [2.49]: $\frac{\varepsilon_{\text{eff}} - \varepsilon_\beta}{\varepsilon_{\text{eff}} + 2\varepsilon_\beta} = \chi_\alpha \frac{\varepsilon_\alpha - \varepsilon_\beta}{\varepsilon_\alpha + 2\varepsilon_\beta}$	
$G(L) = \delta \left(L - \frac{1 - \chi_\alpha}{3} \right)$	
Mixture rule by <i>Looyenga</i> [2.50]: $\varepsilon_{\text{eff}}^{1/3} = \chi_\alpha \varepsilon_\alpha^{1/3} + \chi_\beta \varepsilon_\beta^{1/3}$	
$G(L) = \chi_\alpha^2 \delta(L) + \frac{3\sqrt{3}}{2\pi} \left(\chi_\beta^2 \left \frac{L-1}{L} \right ^{1/3} + \chi_\alpha \chi_\beta \left \frac{L-1}{L} \right ^{2/3} \right)$	
Mixture rule by <i>Monecke</i> [2.51]: $\varepsilon_{\text{eff}} = \frac{2(\chi_\alpha \varepsilon_\alpha + \chi_\beta \varepsilon_\beta)^2 + \varepsilon_\alpha \varepsilon_\beta}{(1 + \chi_\alpha) \varepsilon_\alpha + (2 - \chi_\alpha) \varepsilon_\beta}$	
$G(L) = \frac{2\chi_\alpha}{1 + \chi_\alpha} \delta(L) + \frac{1 - \chi_\alpha}{1 + \chi_\alpha} \delta \left(L - \frac{1 + \chi_\alpha}{3} \right)$	
Mixture rule for hollow sphere equivalent by <i>Bohren and Huffman</i> [2.52]	
$\varepsilon_{\text{eff}} = \varepsilon_\alpha \frac{(3-2f)\varepsilon_\beta + 2f\varepsilon_\alpha}{f\varepsilon_\beta + (3-f)\varepsilon_\alpha}$	
$G(L) = \frac{2}{3-f} \delta(L) + \frac{1-f}{3-f} \delta \left(L - \frac{3-f}{3} \right)$	
where $f = 1 - \frac{r_i^3}{r_o^3}$ and $r_{i/o}$ is the inner/outer radius of the sphere	

tem. Although the spectral function $G(L)$ is generally unknown for an arbitrary two-phase composite, it's analytically known or can be numerically derived

for any existing mixture rule. Examples of spectral functions and corresponding solutions are shown in Table 2.7.

2.9 The Hall Effect

The Hall effect is closely related to the phenomenon of conductivity and is observed as the occurrence of a voltage appearing across a conductor carrying an electric current in a magnetic field. The schematic of the experiment is shown in the Fig. 2.14. The effect is often characterized by the *Hall coefficient*

$$R_H = \frac{E_y}{J_x B_z}, \quad (2.60)$$

where E_y is the Hall effect electric field in the y -direction, J_x is the current density in the

x -direction and B_z is magnetic field in the z -direction.

Fig. 2.14 Hall effect for ambipolar conduction. The magnetic field B_z is out of the plane of the paper. Both electrons and holes are deflected toward the bottom surface of the conductor and so the Hall voltage depends on the relative mobilities and concentrations of electrons and holes

The *Hall effect for ambipolar conduction* in a sample where there are both negative and positive charge carriers, e.g. electrons and holes in a semiconductor, involves not only the concentrations of electrons and holes, n and p respectively, but also the electron and hole drift mobilities, μ_e and μ_h . In the first approximation, the Hall coefficient can be calculated in the following way. Both charge carriers experience a Lorentz force in the same direction since they are drifting in the opposite directions but of course have opposite signs as illustrated in Fig. 2.14. Thus, both holes and electrons accumulate near the bottom surface. The magnitude of the Lorentz force, however, will be different since the drift mobilities and hence drift velocities will be different. Once equilibrium is reached, there should be no current flowing in the y -direction as we have an open circuit. The latter physical arguments lead to the following Hall coefficient [2.5],

$$R_H = \frac{p\mu_h^2 - n\mu_e^2}{e(p\mu_h + n\mu_e)^2}$$

or
$$R_H = \frac{p - nb^2}{e(p + nb)^2}, \quad (2.61)$$

where $b = \mu_e/\mu_h$.

It is clear that the Hall coefficient depends on both the drift mobility ratio and the concentrations of holes and electrons. For $p > nb^2$, R_H will be positive and for $p < nb^2$, it will be negative. Note that the carrier concentration is not zero when the Hall coefficient is zero but rather $n/p = (\mu_h/\mu_e)^2$. As an example, Fig. 2.15 shows the dependence of Hall coefficient vs. electron concentration for a single crystal silicon. The calculations are based on (2.61) and the law of mass action

$$np = n_i^2, \quad (2.62)$$

where n_i is the electron concentration in the intrinsic semiconductor.

In the case of *monopolar conduction*, e.g. conduction in metals or in doped semiconductors, (2.61) reduces to

$$R_H = -\frac{1}{en}, \quad (\text{for } n \gg p) \quad (2.63)$$

or

$$R_H = \frac{1}{ep}, \quad (\text{for } p \gg n). \quad (2.64)$$

Fig. 2.15 Normalized Hall coefficient versus normalized electron concentration plot for single-crystal silicon. The values 0.17, 1.14 and 0.33 shown are the n/n_i values when the magnitude R reaches maxima and zero respectively. In single-crystal silicon, $n_i = 1.5 \times 10^{10} \text{ cm}^{-3}$, $\mu_e = 1350 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and $\mu_h = 450 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$

Therefore, (considering as an example a n -type semiconductor where $\sigma = ne\mu_n$) one can write

$$\mu_H = \frac{\sigma}{ne} = -\sigma R_H \quad (2.65)$$

which provides a simple expression for determining the electron mobility known as the *Hall mobility*. Note, however, that the Hall mobility may differ from the drift mobility discussed in the previous sections. The difference arises from the carriers in a semiconductor having a distribution of energies. An average is used to describe the effect of carriers occupying different allowed states. (This is distinct from the earlier discussions of mobility where it was assumed that all the carriers have the same mean free time between collisions.) To include this, it is necessary to use a formal analysis based on the Boltzmann transport equation, as discussed in Sect. 2.6. If we express the averaging of the carriers with energy E and distribution function $f(E)$, we can write the energy-averaged $\tau(E)$ (i. e., $\langle \tau \rangle$) as:

$$\langle \tau \rangle = \frac{\int \tau(E) f(E) dE}{\int f(E) dE} \quad (2.66)$$

and the energy-averaged τ^2 (i. e., $\langle \tau^2 \rangle$) as:

$$\langle \tau^2 \rangle = \frac{\int \tau^2(E) f(E) dE}{\int f(E) dE}. \quad (2.67)$$

The rigorous analysis [2.12] shows that the Hall mobility μ_H in terms of the drift mobility μ_d is

$$\mu_H = r_H \times \mu_d, \quad (2.68)$$

where r_H is the *Hall factor* given by the ratio

$$r_H = \frac{\langle \tau^2 \rangle}{\langle \tau \rangle^2}. \quad (2.69)$$

2.10 High Electric Field Transport

The previous sections focused on carrier transport in weak electric fields where the energy gained by carriers from the field is lost to the lattice through collisions with phonons or ionized impurities. However at higher fields, the efficiency of collision mechanisms diminishes and the carrier system contains more energy than the lattice. The carriers are then called *hot* with effective temperatures T_e for electrons and T_h for holes. In this case, the drift velocity no longer obeys Ohm's law, and becomes non-linear in the applied field with a clear tendency to saturation due to the appearance of a new dissipation mechanism involving optical phonon generation. Figure 2.16 shows the drift velocity saturation for both electrons and holes in Si and electrons in GaAs; GaAs shows a region of electron velocity overshoot and then negative differential resistivity due to inter-valley scattering, i. e., the transfer of electrons from the Γ minimum to the L conduction band minimum.

Solving the Boltzmann transport equation by analogy with (2.6, 2.7) the mobility may be defined as

$$\mu = \frac{e \langle \tau(T_e) \rangle}{m^*}, \quad (2.70)$$

where e is electron charge and m_e^* is the effective mass and $\langle \tau(T_e) \rangle$ is the mean free time which now strongly de-

pends on T_e . Therefore, the high-field mobility is related to the low field mobility μ_0 by

$$\mu = \mu_0 \left(\frac{T_e}{T} \right)^\beta, \quad (2.71)$$

where β depends on electric field and scattering mechanisms. Thus, in order to determine the dependence of the mobility on electric field, the dependence of the effective carrier temperature on field is required. This may be found by using the time-dependent Boltzmann transport equation. Suppose that F is the field, then for non-degenerate conditions with $T_e \gg T$

$$\frac{T_e}{T} \propto F^{-\frac{2}{2\beta-1}} \quad (2.72)$$

and hence

$$\mu(E) \propto \mu_0 F^{-\frac{2}{2\beta-1}}. \quad (2.73)$$

For acoustic phonon scattering, $\beta = -3/2$ and the drift mobility shows no saturation, increasing with field as $F^{1/4}$. Saturation in the drift velocity may be achieved only when $\beta \rightarrow \infty$ due to optical phonon scattering where large energy changes are involved. The saturation velocity v_s (related to the saturation mobility as $v_s = F\mu_s$) may be calculated using the energy and momentum rate equations for optical phonon scattering:

$$\frac{d\langle E \rangle}{dt} = eFv_s - \frac{E_{op}}{\tau_e} \quad (2.74)$$

$$\frac{d\langle m^* v_s \rangle}{dt} = eF - \frac{m^* v_s}{\tau_m} \quad (2.75)$$

where E_{op} is the optical phonon energy, τ_e and τ_m are the energy and momentum relaxation times, respectively. At steady state and for not extremely high fields, one may assume that $\tau_e \approx \tau_m$. (It is worth noting that at the high-electric fields $\tau_e > \tau_m$ and may lead to the appearance of avalanche, as discussed in Sect. 2.11). Therefore, the solution of (2.74, 2.75) is

$$v_s = \left(\frac{E_{op}}{m^*} \right)^{1/2}. \quad (2.76)$$

in agreement with the experimental values shown in Fig. 2.16.

Fig. 2.16 Dependence of carrier drift velocity on electric field for GaAs and Si [2.53]

2.11 Avalanche

At very high electric field (in the range 2×10^5 V/cm or larger) a new possibility appears: a carrier may have kinetic energy in excess of the binding energy of a valence electron to its parent atom. In colliding with an atom, such a carrier can break the covalent bond and produce an electron-hole pair. This process is called *impact ionization* and is characterized by the *impact ionization coefficient* α (α_e for electrons and α_h for holes). The released electrons and holes may, in turn, impact ionize more atoms producing new electron-hole pairs. This process is called *avalanche* and is characterized by the *multiplication factor*, M which is the ratio of number of collected carriers to the number of initially injected carriers.

The field dependence of the impact ionization coefficient, at least over the limited fields where avalanche

is observed, is usually modeled by experimentalists by using

$$\alpha = A \exp \left[- \left(\frac{B}{F} \right)^n \right], \quad (2.77)$$

where F is the field A , B , n are constants that depend on the semiconductor material properties such as the E - k electronic structure, phonon energies and spectra, scattering mechanisms and so on. The constant B has been semiquantitatively argued to depend on E_g/τ where E_g is the bandgap and $1/\tau$ is the phonon scattering rate; higher bandgap semiconductors tend to have steeper slopes on $\log \alpha$ vs. $1/F$ plots and the $\log \alpha$ vs. $1/F$ curve tends to shift to higher fields. Typically, it has been found that $n \approx 1$ at low fields and $n \approx 2$ for high fields. Figure 2.17 shows experimental data for a variety of materials over a wide range of electric fields.

The origin of (2.77) in its simple $n = 1$ form lies in Shockley's [2.64] *lucky electron* model. When a carrier moves a distance z down-stream (along the field) without being scattered, it gains an energy eFz . An unlucky carrier is scattered so frequently that its eFz never reaches the threshold ionization energy E_I for impact ionization. On the other hand, a *lucky electron* is a ballistic electron that avoids scattering for a substantial distance, and hence is able to build its eFz to reach E_I and thereby cause impact ionization. If λ is the mean free path of collisions, then Shockley's model gives

$$\alpha = \frac{eF}{E_I} \exp \left(- \frac{E_I}{e\lambda F} \right). \quad (2.78)$$

The main problem with the Shockley model is that there are just not enough ballistic electrons to cause sufficient impact ionizations to explain the experiments. A better model was developed by Baraff [2.65] who numerically solved the Boltzmann transport equation for a simple parabolic band and energy independent mean free path to provide a relationship between α and F in terms of four parameters, that is, threshold energy for impact ionization, mean free path associated with ionizations, optical phonon energy, and mean free path for optical phonon scattering. Baraff's theory served experimentalists quite well in terms of comparing their results even though the model was not intuitive and was limited in terms of its assumptions and applicability to real semiconductors.

Impact ionization theory in crystalline solids only reached an acceptable level of confidence and understanding in the 1980s and 1990s with the development of the lucky-drift model by Ridley [2.66] and its extension

Fig. 2.17 Semilogarithmic plot of the dependence of the impact ionization coefficient on the reciprocal field for not only a-Se and a-Si:H, but also for various crystalline semiconductors for comparison; H indicates holes and E electrons. The y-axis is a base-10 logarithm of α in which α is in $1/\text{cm}$. Data for a-Si:H from [2.54]; a-Se electrons and holes from [2.55]; a-Se holes from [2.56], from which α_h was obtained by reanalyzing their multiplication data. Data for crystalline semiconductors are for GaP [2.57]; GaInP ($\text{Ga}_{0.52}\text{In}_{0.48}\text{P}$) [2.58]; $\text{Al}_{0.60}\text{Ga}_{0.40}\text{As}$, [2.59]; InP, [2.60]; Si, [2.61]; GaN (calculation only), [2.62]. Solid circle: Electrons in a-Se [2.55]; Solid square: electrons in a-Si:H [2.54]; Open circle: holes in a-Se [2.55]; Open square: holes in a-Se [2.63]

by Burt [2.67], and Mackenzie and Burt [2.68]. The latter major advancement in the theory appeared as the *lucky drift (LD) model*, and it was based on the realization that at high fields, hot electrons do not relax momentum and energy at the same rates. Momentum relaxation rate is much faster than the energy relaxation rate. An electron can drift, being scattered by phonons, and have its momentum relaxed, which controls the drift velocity, but it can still gain energy during this drift. Stated differently, the mean free path λ_E for energy relaxation is much longer than the mean free path λ for momentum relaxation.

In the Mackenzie and Burt [2.68] version of the LD model, the probability $P(E)$ that a carrier attains an energy E is given by,

$$P(E) = \exp\left(-\int_0^E \frac{dE'}{eF\lambda(E')}\right) + \int_0^E \frac{dE_1}{eF\lambda(E_1)} \times \exp\left(-\int_0^{E_1} \frac{dE'}{eF\lambda(E')}\right) \times \exp\left(-\int_{E_1}^E \frac{dE'}{eF\lambda_E(E')}\right), \quad (2.79)$$

where as mentioned above λ is the mean free path associated with momentum relaxing collisions and λ_E is the mean energy relaxation length associated with the energy relaxing collisions. The first term is the Shockley lucky electron probability, i.e. the electron moves ballistically to energy E . The second term is the lucky drift probability term which is composed of the following: the electron first moves ballistically to some intermediate energy E_1 ($0 < E_1 < E$) from where it begins its lucky drift to energy E_1 ; hence the integration over all possible E_1 . The impact ionization coefficient can then

readily be evaluated from

$$\alpha = \frac{eFP(E_1)}{E_1 \int_0^{E_1} P(E) dE}. \quad (2.80)$$

The model above is based on a hard threshold ionization energy E_1 , that is, when a carrier attains the energy E_1 , ionization ensues. The model has been further refined by the inclusion of soft threshold energies which represent the fact the ionization does not occur immediately when the carrier attains the energy E_1 , and the carrier drifts further to gain more energy than E_1 before impact ionization [2.69–71].

Assuming λ and λ_E are energy independent, which would be the case for a single parabolic band in the crystalline state, (2.79) and (2.80) can be solved analytically to obtain

$$\alpha = \frac{1}{\lambda} \times \frac{\frac{\lambda}{\lambda_E} \exp\left(\frac{-E_1}{eF\lambda_E}\right) + \left(\frac{\lambda}{\lambda_E}\right)^2 \exp\left(\frac{-E_1}{eF\lambda}\right)}{1 - \exp\left(\frac{-E_1}{eF\lambda_E}\right) - \left(\frac{\lambda}{\lambda_E}\right)^2 \left[1 - \exp\left(\frac{-E_1}{eF\lambda}\right)\right]}. \quad (2.81)$$

For $\lambda_E > \lambda$, and in the “low field region”, where typically $(\alpha\lambda) < 10^{-1}$, or $x = E_1/eF\lambda > 10$, (2.81) leads to a simple expression for α ,

$$\alpha = \left(\frac{1}{\lambda_E}\right) \exp\left(-\frac{E_1}{eF\lambda_E}\right). \quad (2.82)$$

For crystalline semiconductors, one typically also assumes that λ_E depends on the field F , λ and the optical phonon energy $\hbar\omega$ as

$$\lambda_E = \frac{eF\lambda^2}{2\hbar\omega} \coth\left(\frac{\hbar\omega}{2kT}\right). \quad (2.83)$$

As the field increases, λ_E eventually exceeds λ , and allows lucky drift to operate and the LD carriers to reach the ionization energy.

It is worth noting that the model of lucky drift is successfully used not only for crystalline semiconductors but to amorphous semiconductors [2.72].

2.12 Two-Dimensional Electron Gas

Heterostructures offer the ability to spatially engineer the potential in which carriers move. In such structures having layers deposited in the z -direction, when the width of a region with confining potential $t_z < \lambda_{dB}$, the de Broglie electron wavelength, electron states become stationary states in that direction, retaining Bloch wave character in the other two directions (i.e., x - and

y -directions), and is hence termed a *2-D electron gas (2DEG)*. These structures are notable for their extremely high carrier mobility.

High mobility structures are formed by selectively doping the wide bandgap material behind an initially undoped spacer region of width d as shown in Fig. 2.18a. Ionization and charge transfer leads to carrier build-up

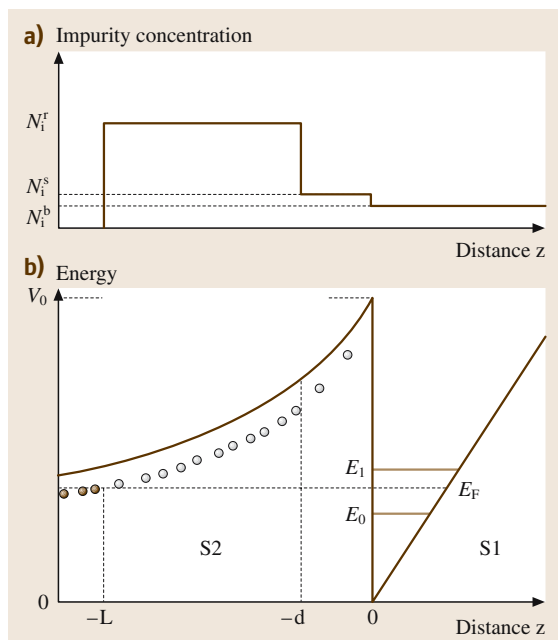

Fig. 2.18 (a) Doping profile for a selectively doped 2DEG heterostructure. The S1 is a narrow bandgap material adjacent to the heterointerface. The S2 is selectively doped wide-bandgap material including an initially undoped spacer region of width d . (b) Conduction energy band structure for a selectively doped 2DEG heterostructure. The equilibrium band bending (through Poisson's equation) in the well region results from the equalization of the ionized donor concentration in the wide-bandgap material and the 2DEG concentration adjacent to the heterointerface. When the associated interfacial field is sufficiently strong, carriers are confined within λ_{dB} and electron states are quantized into the sub-bands E_0 and E_1 [2.73]

in the low potential region of narrow bandgap material adjacent to the hetero-interface. The equilibrium band bending (i.e., through Poisson's equation) in the well region, as shown in Fig. 2.18b, results from the equalization of ionized donor concentration in the wide bandgap material and 2DEG concentration adjacent to the heterointerface. When the associated interfacial field is sufficiently strong, carriers are confined within λ_{dB} and electron states are quantized into sub-bands (i.e., E_0 and E_1), as shown in Fig. 2.18b.

Figure 2.19 shows the contributions of component scattering mechanisms to the low temperature mobility of a 2DEG formed at a $\text{Ga}_{0.70}\text{Al}_{0.3}\text{As}$ -GaAs heterointerface, as a function of the electron gas density. As for bulk samples, the most important mechanism limiting

Fig. 2.19 Dependence of 2DEG electron mobility on carrier concentration for a $\text{Ga}_{0.70}\text{Al}_{0.3}\text{As}$ -GaAs heterostructure [2.73]

the low temperature mobility is ionized impurity scattering, except at high electron densities, where so-called *alloy disorder scattering* is significant. Ionized impurity scattering may be further broken down into scattering from ionized impurities that are with the GaAs quantum well, known as *background impurities*, those beyond the spacer region, termed *remote impurity scattering*. For high purity growth, the unintentional background impurity concentration can be kept to very low limits and impurity scattering based mobility values are then dictated by remote impurity scattering. Since carriers in the well are only weakly scattered by the tail field of these remote Coulomb centers, the mobility of such 2DEG systems can be orders of magnitude higher than bulk samples. The temperature dependence of the electron mobility for such a system is shown in Fig. 2.20. Notice how, similar to bulk sample, increasing temperature

Fig. 2.20 Dependence of 2DEG electron mobility on temperature for a $\text{Ga}_{0.70}\text{Al}_{0.3}\text{As-GaAs}$ heterostructure [2.73]

increases the phonon population such that for the example shown, above about 100 K, polar optical phonon scattering controls the mobility.

Figure 2.21 shows the dependence of the 2DEG mobility on the spacer width. Two competing factors are active – for narrow spacer widths, the transfer efficiency of carriers to the GaAs well is high and so a lower remote doping concentration is sufficient to provide for a given constant 2DEG concentration, but since the Coulomb

Fig. 2.21 Dependence of 2DEG electron mobility on spacer width for a $\text{Ga}_{0.70}\text{Al}_{0.3}\text{As-GaAs}$ heterostructure [2.73]

scatters are so close to the 2DEG, they scatter very efficiently and limit the mobility. On the other hand, for large spacer widths, carrier transfer efficiency is quite poor requiring higher remote doping to supply the given 2DEG concentration; however, being relatively far away each of the scattering centers are less effective at lowering the mobility, but given their high concentration, the net effect is still a decrease in the mobility at large spacer widths as seen in the figure.

2.13 One Dimensional Conductance

In the case where carriers are confined within regions of width L_x , $L_y < \lambda_{dB}$ in two directions x and y , respectively, the electron energy in those two directions become quantized with quantum numbers n_x and n_y , respectively. In the third direction z , electrons travel as Bloch waves with energy that may be approximated by

$\hbar^2 k_z^2 / 2m^*$ giving an expression for the total energy E of the so-called *I-D electron system* or *quantum wire* as:

$$E(n_x, n_y, n_z) = \frac{\hbar^2 \pi^2}{2m^*} \left(\frac{n_x^2}{L_x^2} + \frac{n_y^2}{L_y^2} \right) + \frac{\hbar^2 k_z^2}{2m^*}. \quad (2.84)$$

The associated electron wavefunctions are:

$$\Psi(x, y, z) = \frac{1}{2\sqrt{L_x L_y L_z}} \sin\left(\frac{n_x \pi x}{L_x}\right) \times \sin\left(\frac{n_y \pi y}{L_y}\right) e^{ik_z z}. \quad (2.85)$$

Using these equations, one can readily derive an expression for the density of states per unit energy range:

$$\begin{aligned} \text{DOS} &= 2 \times 2 \left(\frac{L_z}{2\pi}\right) (\nabla_{k_z} E)^{-1} \\ &= \frac{2L_z}{h} \sqrt{\frac{m^*}{2(E - E_{n_x, n_y})}}. \end{aligned} \quad (2.86)$$

In order to evaluate the conductance of this quantum wire, consider the influence of a weak applied potential V . Similar to the case for bulk transport the applied field displaces the *Fermi surface* and results in a change in the electron wave-vector from k_0 (i. e., with no applied potential) to k_V (i. e., when the potential is applied). When V is small compared with the electron energy:

$$k_0 = \sqrt{\frac{2m^*(E - E_{n_x, n_y})}{\hbar^2}}, \quad (2.87)$$

$$\begin{aligned} k_V &= k_0 \sqrt{1 + \frac{eV}{E - E_{n_x, n_y}}} \\ &\approx k_0 \left(1 + \frac{1}{2} \frac{eV}{E - E_{n_x, n_y}}\right). \end{aligned} \quad (2.88)$$

This leads to establishing a current density J in the wire

$$J = \frac{2e^2 (\text{DOS}) \sqrt{(E_F - E_{n_x, n_y})}}{\sqrt{2m^*}}. \quad (2.89)$$

Which may be simplified to the following expressions for J and the current flowing in the wire for a given quantum state $E\{n_x, n_y\}$, I

$$J_{n_x, n_y} = \frac{2e^2 V L_z}{h} \quad \text{and} \quad I_{n_x, n_y} = \frac{2e^2 V}{h}. \quad (2.90)$$

The expression for the conductance through one channel corresponding to a given quantum state $\{n_x, n_y\}$ is then given by

$$G_{n_x, n_y} = \frac{I_{n_x, n_y}}{V} = \frac{2e^2}{h}. \quad (2.91)$$

Notice how the conductance is quantized in units of e^2/h with each populated channel contributing equally to the conductance – moreover, this is a fundamental result, being independent of the material considered. In practice, deviations from this equation can occur (although generally less than 1%) owing to the finiteness of real nanowires and impurities in or near the channel, influencing the conductivity and even resulting in weak localization. Generally, unlike both bulk and 2DEG systems, ionized impurity scattering is suppressed in nanowires. The main reason for this is that an incident electron in a quantum state $\{n_x, n_y\}$ traveling along the wire with wave-vector $k_z\{n_x, n_y\}$, can not be elastically scattered into any states except those in a small region of k -space in the vicinity of $-k_z\{n_x, n_y\}$. Such a scattering event involves a large change in momentum of $\approx 2k_z\{n_x, n_y\}$ and thus, the probability of such events is very small. As a result, the mean free path and mobility of carriers in such quantum wires are substantially increased.

The nature of carrier transport in quantum wires depends on the wire dimensions (i. e., length L_{Wire} and diameter d_{Wire}) as compared with the carrier mean free path, l_{Carrier} . When $l_{\text{Carrier}} \gg L_{\text{Wire}}, d_{\text{Wire}}$ the only potential seen by the carriers is that associated with the wire walls, and carriers exhibit wavelike behavior, being guided through the wire as if it were a waveguide without any internal scattering. Conversely, if $d_{\text{Wire}} \ll \lambda_{\text{DeBroglie}}$, only a few energy states in the wire are active, and in the limit of an extremely small waveguide, only one state or channel is active, analogous to a single mode waveguide cavity – this case is termed *quantum ballistic transport*. In the limit, $l_{\text{Carrier}} \ll L_{\text{Wire}}, d_{\text{Wire}}$, scattering dominates transport throughout the wire – with numerous scattering events occurring before a carrier can traverse the wire or move far along its length. In such a case the transport is said to be *diffusive*. As discussed previously, ionized impurity and lattice scattering contribute to l_{Carrier} , with l_{Carrier} decreasing with increasing temperature due to phonon scattering. For strong impurity scattering, this may not occur until relatively high temperatures. In the intermediate case of $L_{\text{Wire}} \gg l_{\text{Carrier}} \gg d_{\text{Wire}}$ and where $d_{\text{Wire}} \ll \lambda_{\text{DeBroglie}}$ scattering is termed “mixed mode” and is often called *quasi-ballistic*.

2.14 The Quantum Hall Effect

The observation of, and first explanation for the Hall Effect in a 2DEG by von Klitzing et al. [2.74], won them a Nobel Prize. As shown in Fig. 2.22 the Hall re-

sistivity exhibits plateaus for integer values of h/e^2 , independent of any material dependent parameters. This discovery was later shown to be correct to a precision

of at least one part in 10^7 , enabling extremely accurate determinations of the fine structure constant (i.e., $\alpha = (\mu_0 c e^2 / 2h) \approx 1/137$) and a fundamental resistance standard to be established.

For the six point Hall geometry used (as shown in the insert to Fig. 2.18), one can define the *Hall resistivity* $\rho_{xy} = g_1 V_{H,y} / I_x$ and *longitudinal resistivity* $\rho_{xx} = g_2 V_{L,x} / I_x$ where g_1 and g_2 are geometric constants related to the sample geometry. These resistivities are related to corresponding conductivities through the conductivity and resistivity tensors

$$\begin{aligned}\rho_{xy} &= \frac{\sigma_{xy}}{\sigma_{xx}^2 + \sigma_{xy}^2}, \\ \rho_{xx} &= \frac{\sigma_{xx}}{\sigma_{xx}^2 + \sigma_{xy}^2}, \\ \rho_{yx} &= -\rho_{xy}, \\ \rho_{yy} &= \rho_{xx}.\end{aligned}\quad (2.92)$$

Starting from a classical equation of motion for electrons in an electric field E_x , magnetic field B_z , and defining the *cyclotron frequency* $\omega_c = eB_z/m^*$, the velocities perpendicular to the applied magnetic field can be deduced as

$$v_x = \frac{E_x}{B_x} \sin \omega_c t \quad \text{and} \quad v_y = \frac{E_x}{B_x} (\cos \omega_c t - 1) \quad (2.93)$$

with the time averaged velocities

$$\langle v_x \rangle = \frac{E_x}{B_x} \quad \text{and} \quad \langle v_y \rangle = \frac{E_x}{B_x} \quad (2.94)$$

leading to Hall and longitudinal resistivities of

$$\sigma_{xx} = \sigma_{yy} = 0 \quad \text{and} \quad \sigma_{xy} = -\sigma_{yx} = \frac{N_s e}{B_z}, \quad (2.95)$$

where N_s is the areal electron concentration. Below, a quantum approach is used to establish a relationship for the electron concentration N_s . Note that the motion of the electrons in the crossed fields are quantized with allowed levels termed *Landau levels* E_n :

$$E_n = \left(n + \frac{1}{2}\right) \hbar \omega_c + g^* \mu_B B_z + \varepsilon_z, \quad (2.96)$$

where n is the quantum number describing the particular Landau Level, g^* is the *Landé factor*, μ_B is the Bohr magneton and $g^* \mu_B B_z$ is the *spin magnetic energy*, and E_z is the energy associated with the z -motion of the carriers. xy -plane carrier motion is characterized by the cyclotron energy term E_{xy} ,

$$E_{xy} = \frac{\hbar^2 k_{xy}^2}{2m_e^*} = \left(n + \frac{1}{2}\right) \hbar \omega_c. \quad (2.97)$$

Following this description and noting that the motion of electrons in the xy -plane may be expressed in terms of wavefunctions of the *harmonic oscillator* using the *Landau gauge* of the *vector potential* $[0, xB_z, 0]$, we may write the density of states per unit area, DOS_A as:

$$\text{DOS}_A = \frac{m_e^* \omega_c L_x L_y}{2\pi \hbar}. \quad (2.98)$$

Since the degeneracy of each Landau level is one (i.e., since they are single spin states), this enables one to find N_s assuming Landau state filling up to the p^{th} level (for integer p):

$$N_s = \frac{m_e^* \omega_c p}{2\pi \hbar}. \quad (2.99)$$

Using the definition of the cyclotron frequency gives the final form

$$N_s = \frac{peB_z}{\hbar} \quad (2.100)$$

which may be used to rewrite the previous expressions for Hall and longitudinal resistivity

$$\rho_{xx} = \rho_{yy} = 0 \quad \text{and} \quad \rho_{xy} = -\rho_{yx} = \frac{h}{pe^2}. \quad (2.101)$$

Fig. 2.22 Hall voltage V_H and voltage drop across electrodes V_{PP} as a function of gate voltage V_g at 1.5 K, when $B = 18$ T. Source-drain current is $1 \mu\text{A}$. Insert shows plan view of a device with length $400 \mu\text{m}$, width $50 \mu\text{m}$ and an interprobe separation of $130 \mu\text{m}$ [2.74]

Equation (2.101) shows that Hall resistivity is quantized in units of h/pe^2 whenever the Fermi energy lies between filled Landau levels. Consistent with observation, the result is independent of the semiconductor being studied. Although this model provides an excel-

lent basis for understanding experiments, understanding the details of the results (i.e., in particular the existence of a finite width for the Hall effect plateaus and zero longitudinal resistance dips) requires a more complete treatment involving so-called localized states.

3. Optical Properties of Electronic Materials: Fundamentals and Characterization

Light interacts with materials in a variety of ways; this chapter focuses on refraction and absorption. Refraction is characterized by a material's refractive index. We discuss some of the most useful models for the frequency dependence of the refractive index, such as those due to Cauchy, Sellmeier, Gladstone–Dale, and Wemple–Di Dominico. Examples are given of the applicability of the models to actual materials. We present various mechanisms of light absorption, including absorption by free carriers, phonons, excitons and impurities. Special attention is paid to fundamental and excitonic absorption in disordered semiconductors and to absorption by rare-earth, trivalent ions due to their importance to modern photonics. We also discuss the effect of an external electric field on absorption, and the Faraday effect. Practical techniques for determining the optical parameters of thin films are outlined. Finally, we present a short technical classification of optical glasses and materials.

3.1 Optical Constants

The changes that light undergoes upon interacting with a particular substance are known as the optical properties of that substance. These optical properties are influenced by the macroscopic and microscopic properties of the substance, such as the nature of its surface and its electronic structure. Since it is usually far easier to detect the way a substance modifies light than to investigate its macroscopic and microscopic properties directly, the optical properties of a substance are often used to probe other properties of the material. There are many optical properties, including the most well known: reflection, refraction, transmission and absorption. Many of these optical properties are associated with important optical constants, such as the refractive index and the extinction

coefficient. In this section we review these optical constants, such as the refractive index and the extinction coefficient. Books by *Adachi* [3.1], *Fox* [3.2] and *Simmons and Porter* [3.3] are highly recommended. In addition, *Adachi* also discusses the optical properties of III–V compounds in this handbook.

3.1.1 Refractive Index and Extinction Coefficient

The refractive index n of an optical or dielectric medium is the ratio of the velocity of light c in vacuum to its velocity v in the medium; $n = c/v$. Using this and Maxwell's equations, one obtains the well-known

formula for the refractive index of a substance as $n = \sqrt{\varepsilon_r \mu_r}$, where ε_r is the static constant or relative permittivity and μ_r is the magnetic permeability. As $\mu_r = 1$ for nonmagnetic substances, one gets $n = \sqrt{\varepsilon_r}$, which is very useful for relating the dielectric properties of a material to its optical properties at any particular frequency of interest. Since ε_r depends on the wavelength of the light, the refractive index depends on it too, which is called dispersion. In addition to dispersion, an electromagnetic wave propagating through a lossy medium (one that absorbs or scatters radiation passing through it) experiences attenuation, which means that it loses its energy due to various loss mechanisms such as the generation of phonons (lattice waves), photogeneration, free carrier absorption and scattering. In such materials, the refractive index is a complex function of the frequency of the light wave.

The complex refractive index N , with real part n and imaginary part K (called the extinction coefficient), is related to the complex relative permittivity, $\varepsilon_r = \varepsilon'_r - i\varepsilon''_r$ by:

$$N = n - iK = \sqrt{\varepsilon_r} = \sqrt{\varepsilon'_r - i\varepsilon''_r} \quad (3.1)$$

where ε'_r and ε''_r are, respectively, the real and imaginary parts of ε_r . Equation (3.1) gives:

$$n^2 - K^2 = \varepsilon'_r \quad \text{and} \quad 2nK = \varepsilon''_r. \quad (3.2)$$

The optical constants n and K can be determined by measuring the reflectance from the surface of a material as a function of polarization and the angle of incidence. For normal incidence, the reflection coefficient r is obtained as:

$$r = \frac{1 - N}{1 + N} = \frac{1 - n + iK}{1 + n - iK}. \quad (3.3)$$

The reflectance R is then defined by:

$$R = |r|^2 = \left| \frac{1 - n + iK}{1 + n - iK} \right|^2 = \frac{(1 - n)^2 + K^2}{(1 + n)^2 + K^2}. \quad (3.4)$$

Notice that whenever K is large, for example over a range of wavelengths, the absorption is strong, and the reflectance is almost unity. The light is then reflected, and any light in the medium is highly attenuated.

Optical properties of materials are typically presented by showing either the frequency dependence (dispersion relation) of n and K or ε'_r and ε''_r . An intuitive guide to explaining dispersion in insulators is based on a single oscillator model in which the electric field in the light induces forced dipole oscillations in the material (displaces the electron shells to oscillate about the nucleus) with a single resonant frequency

ω_0 [3.1]. The frequency dependences of ε'_r and ε''_r are then obtained as:

$$\varepsilon'_r = 1 + \frac{N_{\text{at}}}{\varepsilon_0} \alpha'_e \quad \text{and} \quad \varepsilon''_r = 1 + \frac{N_{\text{at}}}{\varepsilon_0} \alpha''_e, \quad (3.5)$$

where N_{at} is the number of atoms per unit volume, ε_0 is the vacuum permittivity, and α'_e and α''_e are the real and imaginary parts of the electronic polarizability, given respectively by:

$$\alpha'_e = \alpha_{e0} \frac{1 - (\omega/\omega_0)^2}{[1 - (\omega/\omega_0)^2]^2 + (\gamma/\omega_0)^2 (\omega/\omega_0)^2}, \quad (3.6a)$$

and

$$\alpha''_e = \alpha_{e0} \frac{(\gamma/\omega_0)(\omega/\omega_0)}{[1 - (\omega/\omega_0)^2]^2 + (\gamma/\omega_0)^2 (\omega/\omega_0)^2}, \quad (3.6b)$$

where α_{e0} is the dc polarizability corresponding to $\omega = 0$ and γ is the loss coefficient. Using (3.1), (3.2) and (3.5), it is then possible to study (3.6a, 6b), the frequency dependence of n and K . Figure 3.1a shows the dependence of n and K on the normalized frequency ω/ω_0 for a simple single electronic dipole oscillator of resonance frequency ω_0 . It is seen that n and K peak close to $\omega = \omega_0$. If a material has a $\varepsilon''_r \gg \varepsilon'_r$, then $\varepsilon_r \approx -i\varepsilon''_r$ and $n = K \approx \sqrt{\varepsilon''_r/2}$ is obtained from (3.2). Figure 3.1b shows the dependence of the reflectance R on the frequency. It is observed that R reaches its

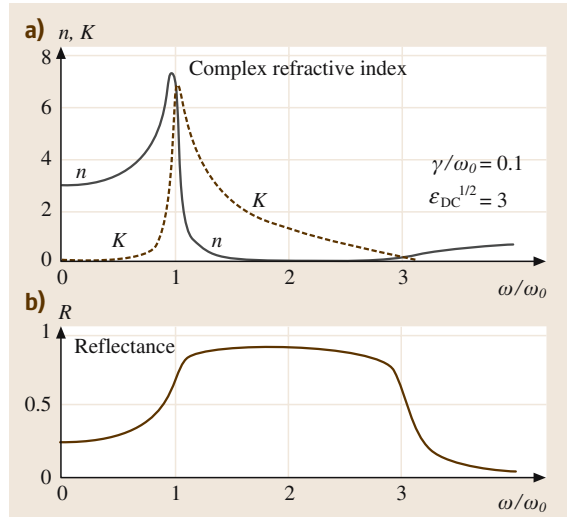

Fig. 3.1a,b The dipole oscillator model. (a) Refractive index and extinction coefficient versus normalized frequency. (b) Reflectance versus normalized frequency

maximum value at a frequency slightly above $\omega = \omega_0$, and then remains high until ω reaches nearly $3\omega_0$; so the reflectance is substantial while absorption is strong. The normal dispersion region is the frequency range below ω_0 where n falls as the frequency decreases; that is, n decreases as the wavelength λ increases. The anomalous dispersion region is the frequency range above ω_0 , where n decreases as ω increases. Below ω_0 , K is small and if ϵ_{dc} is $\epsilon_r(0)$, the refractive index becomes:

$$n^2 \approx 1 + (\epsilon_{dc} - 1) \frac{\omega_0^2}{\omega_0^2 - \omega^2}; \quad \omega < \omega_0. \quad (3.7)$$

Since, $\lambda = 2\pi c/\omega$, defining $\lambda_0 = 2\pi c/\omega_0$ as the resonance wavelength, one gets:

$$n^2 \approx 1 + (\epsilon_{dc} - 1) \frac{\lambda^2}{\lambda^2 - \lambda_0^2}; \quad \lambda > \lambda_0. \quad (3.8)$$

While intuitively useful, the dispersion relation in (3.8) is far too simple. More rigorously, we have to consider the dipole oscillator quantum-mechanically, which means that a photon excites the oscillator to a higher energy level; see, for example, [3.2, 3]. The result is that we have a series of $\lambda^2/(\lambda^2 - \lambda_i^2)$ terms with various weighting factors A_i that add to unity, where the λ_i represent different resonance wavelengths. The weighting factors A_i involve quantum-mechanical matrix elements.

Figure 3.2 shows the complex relative permittivity and the complex refractive index of crystalline silicon in terms of photon energy $h\nu$. For photon energies below the bandgap energy (1.1 eV), both ϵ_r'' and K are negligible and n is close to 3.7. Both ϵ_r'' and K increase and change strongly as the photon energy becomes greater than 3 eV, far beyond the bandgap energy. Notice that both ϵ_r' and n peak at $h\nu \approx 3.5$ eV, which corresponds to a direct photoexcitation process – the excitation of electrons from the valence band to the conduction band – as discussed later.

3.1.2 Kramers–Kronig Relations

If we know the frequency dependence of the real part, ϵ_r' , of the relative permittivity of a material, then we can use the Kramers–Kronig relations to determine the frequency dependence of the imaginary part ϵ_r'' , and vice versa. The transform requires that we know the frequency dependence of either the real or imaginary part over a frequency range that is as wide as possible, ideally from dc to infinity, and that the material is linear; in

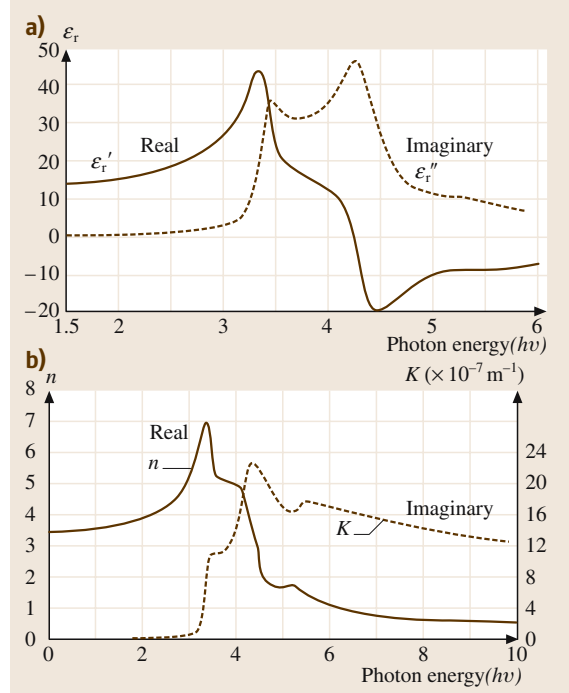

Fig. 3.2 (a) Complex relative permittivity of a silicon crystal as a function of photon energy plotted in terms of real (ϵ_r') and imaginary (ϵ_r'') parts. (b) Optical properties of a silicon crystal versus photon energy in terms of real (n) and imaginary (K) parts of the complex refractive index. After [3.4]

other words it has a relative permittivity that is independent of the applied field. The Kramers–Kronig relations for $\epsilon_r = \epsilon_r' + i\epsilon_r''$ are given by [3.4]:

$$\epsilon_r'(\omega) = 1 + \frac{2}{\pi} P \int_0^{\infty} \frac{\omega' \epsilon_r''(\omega')}{\omega'^2 - \omega^2} d\omega', \quad (3.9a)$$

and

$$\epsilon_r''(\omega) = -\frac{2\omega}{\pi} P \int_0^{\infty} \frac{\epsilon_r'(\omega')}{\omega'^2 - \omega^2} d\omega', \quad (3.9b)$$

where ω' is the integration variable, P represents the Cauchy principal value of the integral and the singularity at $\omega = \omega'$ is avoided.

Similarly, one can relate the real and imaginary parts of the polarizability, $\alpha'(\omega)$ and $\alpha''(\omega)$, and those of the

complex refractive index, $n(\omega)$ and $K(\omega)$ as well. For $\alpha'(\omega)$ and $\alpha''(\omega)$, one can analogously write:

$$\alpha'(\omega) = \frac{2}{\pi} P \int_0^{\infty} \frac{\omega' \alpha''(\omega')}{\omega'^2 - \omega^2} d\omega' \quad (3.10a)$$

$$\alpha''(\omega') = -\frac{2\omega}{\pi} P \int_0^{\infty} \frac{\alpha'(\omega')}{\omega'^2 - \omega^2} d\omega' . \quad (3.10b)$$

3.2 Refractive Index

There are several simplified models describing the spectral dependence of the refractive index n .

3.2.1 Cauchy Dispersion Equation

The dispersion relationship for the refractive index (n) versus the wavelength of light (λ) is stated in the following form:

$$n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} , \quad (3.11)$$

where A , B and C are material-dependent specific constants. The Cauchy equation (3.11) is typically used in the visible region of the spectrum for various optical glasses, and is applied to normal dispersion. The third term is sometimes dropped for a simpler representation of n versus λ behavior. The original expression was a series in terms of the wavelength, λ , or frequency, ω , of

light as:

$$n = a_0 + a_2 \lambda^{-2} + a_4 \lambda^{-4} + a_6 \lambda^{-6} + \dots \lambda > \lambda_h , \quad (3.12a)$$

or

$$n = n_0 + n_2 \omega^2 + n_4 \omega^4 + n_6 \omega^6 + \dots \omega < \omega_h , \quad (3.12b)$$

where $\hbar\omega$ is the photon energy, $\hbar\omega_h = hc/\lambda_h$ is the optical excitation threshold (the bandgap energy), while a_0 , $a_2 \dots$, and n_0, n_2, \dots are constants. A Cauchy relation of the following form:

$$n = n_{-2}(\hbar\omega)^{-2} + n_0 + n_2(\hbar\omega)^2 + n_4(\hbar\omega)^4 , \quad (3.13)$$

can be used satisfactorily over a wide range of photon energies. The dispersion parameters, calculated from (3.13), of a few materials are listed in Table 3.1.

Table 3.1 Cauchy's dispersion parameters (obtained from (3.11)) for a few materials

Cauchy's dispersion relation, given in (3.13), was originally called the elastic-ether theory of the refractive index [3.5–7]. It has been widely used for many materials, although in recent years it has been largely replaced by the Sellmeier equation, which we consider next.

3.2.2 Sellmeier Dispersion Equation

The dispersion relationship can be quite complicated in practice. An example of this is the Sellmeier equation, which is an empirical relation between the refractive index n of a substance and the wavelength λ of light in the form of a series of $\lambda^2/(\lambda^2 - \lambda_i^2)$ terms, given by:

$$n^2 = 1 + \frac{A_1\lambda^2}{\lambda^2 - \lambda_1^2} + \frac{A_2\lambda^2}{\lambda^2 - \lambda_2^2} + \frac{A_3\lambda^2}{\lambda^2 - \lambda_3^2} + \dots, \quad (3.14)$$

where λ_i is a constant and $A_1, A_2, A_3, \lambda_1, \lambda_2$ and λ_3 are called Sellmeier coefficients, which are determined by fitting this expression to the experimental data. The full Sellmeier formula has more terms of similar form, such as $A_i\lambda^2/(\lambda^2 - \lambda_i^2)$, where $i = 4, 5, \dots$ but these can generally be neglected when considering n versus λ behavior over typical wavelengths of interest and by ensuring that the three terms included in the Sellmeier equation correspond to the most important or relevant terms in the summation. Examples of Sellmeier coefficients for some materials, including pure silica (SiO_2) and 86.5 mol.% SiO_2 -13.5 mol.% GeO_2 , are given in Table 3.2. Two methods are used to find the refractive index of silica-germania glass (SiO_2)_{1-x}(GeO_2)_x: (a) a simple, but approximate, linear interpolation of the refractive index between known compositions, for example $n(x) - n(0.135) = (x - 0.135)[n(0.135) - n(0)]/0.135$ for (SiO_2)_{1-x}(GeO_2)_x, so $n(0.135)$ is used for 86.5 mol.% SiO_2 -13.5 mol.% GeO_2 and $n(0)$ is used for SiO_2 ; (b) an interpolation for the coefficients A_i and λ_i between SiO_2 and GeO_2 :

$$n^2 - 1 = \frac{\{A_1(S) + X[A_1(G) - A_1(S)]\}\lambda^2}{\lambda^2 - \{\lambda_1(S) + X[\lambda_1(G) - \lambda_1(S)]\}^2} + \dots, \quad (3.15)$$

where X is the atomic fraction of germania, S and G in parentheses refer to silica and germania [3.10]. The theoretical basis of the Sellmeier equation is that the solid is represented as a sum of N lossless (frictionless) Lorentz oscillators such that each takes the form of $\lambda^2/(\lambda^2 - \lambda_i^2)$ with different λ_i , and each has different strengths, with weighting factors ($A_i, i = 1$ to N) [3.11, 12]. Knowledge of appropriate dispersion relationships is essential when designing photonic devices, such as waveguides.

There are other dispersion relationships that inherently take account of various contributions to optical properties, such as the electronic and ionic polarization and the interactions of photons with free electrons. For example, for many semiconductors and ionic crystals, two useful dispersion relations are:

$$n^2 = A + \frac{B\lambda^2}{\lambda^2 - C} + \frac{D\lambda^2}{\lambda^2 - E}, \quad (3.16)$$

and

$$n^2 = A + \frac{B}{\lambda^2 - \lambda_0^2} + \frac{C}{(\lambda^2 - \lambda_0^2)^2} + D\lambda^2 + E\lambda^4, \quad (3.17)$$

where A, B, C, D, E and λ_0 are constants particular to a given material. Table 3.3 provides a few examples.

The refractive index of a semiconductor material typically decreases with increasing bandgap energy E_g . There are various empirical and semi-empirical rules and expressions that relate n to E_g . In *Moss' rule*, n and E_g are related by $n^4 E_g = K = \text{constant}$ (≈ 100 eV). In the *Hervé-Vandamme* relationship [3.13],

$$n^2 = 1 + \left(\frac{A}{E_g + B} \right)^2, \quad (3.18)$$

where A and B are constants ($A \approx 13.6$ eV and $B \approx 3.4$ eV and $\text{dB}/\text{dT} \approx 2.5 \times 10^{-5}$ eV/K). The refractive index typically increases with increasing temperature. The temperature coefficient of the refractive index (TCRI) of a semiconductor can be found from the Hervé-Vandamme relationship [3.13]:

$$\text{TCRI} = \frac{1}{n} \cdot \frac{dn}{dT} = \frac{(n^2 - 1)^{3/2}}{13.6n^2} \left(\frac{dE_g}{dT} + \frac{dB}{dT} \right). \quad (3.19)$$

CdSe	4	2	8	4.0	20.6	0.32	$\beta_i - \beta_c$	Wurtzite

TCRI is typically in the range 10^{-6} to 10^{-4} .

3.2.3 Gladstone–Dale Formula

The *Gladstone–Dale formula* is an empirical equation that allows the average refractive index n of an oxide glass to be calculated from its density ρ and its constituents as:

$$\frac{n-1}{\rho} = p_1 k_1 + p_2 k_2 + \dots = \sum_{i=1}^N p_i k_i = C_{GD}, \quad (3.20)$$

where the summation is for various oxide components (each a simple oxide), p_i is the weight fraction of the i -th oxide in the compound, and k_i is the refraction coefficient that represents the polarizability of the i -th oxide. The right hand side of (3.20) is called the Gladstone–Dale coefficient C_{GD} . In more general terms, as a mixture rule for the overall refractive index, the Gladstone–Dale formula is frequently written as:

$$\frac{n-1}{\rho} = \frac{n_1-1}{\rho_1} w_1 + \frac{n_2-1}{\rho_2} w_2 + \dots, \quad (3.21)$$

where n and ρ are the effective refractive index and effective density of the whole mixture, n_1 , n_2 ,

... are the refractive indices of the constituents, and ρ_1 , ρ_2 , ... represent the densities of each constituent. Gladstone–Dale equations for the polymorphs of SiO₂ and TiO₂ give the average n values as [3.14]:

$$n(\text{SiO}_2) = 1 + 0.21\rho \quad \text{and} \quad n(\text{TiO}_2) = 1 + 0.40\rho. \quad (3.22)$$

3.2.4 Wemple–Di Dominico Dispersion Relation

The *Wemple–Di Dominico dispersion relation* is a semi-empirical single oscillator-based relationship used to find the refractive indices of a variety of materials for photon energies below the interband absorption edge, given by

$$n^2 = 1 + \frac{E_0 E_d}{E_0^2 - (h\nu)^2}, \quad (3.23)$$

where ν is the frequency, h is the Planck constant, E_0 is the single oscillator energy, E_d is the dispersion energy, which is a measure of the average strength of interband optical transitions; $E_d = \beta N_c Z_a N_c$ (eV), where N_c is the effective coordination number of the cation nearest-neighbor to the anion ($N_c = 6$ in NaCl, $N_c = 4$

in Ge), Z_a is the formal chemical valency of the anion ($Z_a = 1$ in NaCl; 2 in Te; 3 in GaP), N_e is the effective number of valence electrons per anion excluding the cores ($N_e = 8$ in NaCl, Ge; 10 in TlCl; 12 in Te; $9\frac{1}{3}$ in As_2Se_3), and β is a constant that depends on whether the interatomic bond is ionic (β_i) or covalent (β_c): $\beta_i = 0.26 \pm 0.04$ eV (this applies to halides such as NaCl and ThBr and most oxides, including Al_2O_3 , for example), while $\beta_c = 0.37 \pm 0.05$ eV (applies to tetrahedrally bonded $A^N B^{8-N}$ zinc blende- and diamond-type structures such as GaP, ZnS, for instance). (Note that wurtzite crystals have a β that is intermediate between β_i and β_c .) Also, empirically, $E_0 = CE_g(D)$, where $E_g(D)$ is the lowest direct bandgap and C is a constant, typically ≈ 1.5 . E_0 has been associated with the main peak in the $\epsilon''_r(h\nu)$ versus $h\nu$ spectrum. The parameters required to calculate n from (3.23) are listed in Table 3.4 [3.15].

3.2.5 Group Index (N_g)

The group index represents the factor by which the group velocity of a group of waves in a dielectric medium is reduced with respect to propagation in free space,

Fig. 3.3 Refractive index n and the group index N_g of pure SiO_2 (silica) glass as a function of wavelength

$N_g = c/v_g$, where v_g is the group velocity. The group index can be determined from the ordinary refractive index n via

$$N_g = n - \lambda \frac{dn}{d\lambda}, \quad (3.24)$$

where λ is the wavelength of light. The relation between N_g and n for SiO_2 is illustrated in Fig. 3.3.

3.3 Optical Absorption

The main optical properties of a semiconductor are typically its refractive index n and its extinction coefficient K or absorption coefficient α (or equivalently the real and imaginary parts of the relative permittivity), as well

Fig. 3.4 Absorption coefficient plotted as a function of the photon energy in a typical semiconductor, illustrating various possible absorption processes

as their dispersion relations (their dependence on the electromagnetic radiation wavelength λ or photon energy $h\nu$) and the changes in the dispersion relations with temperature, pressure, alloying, impurities, and so on. A typical relationship between the absorption coefficient and the photon energy observed in a crystalline semiconductor is shown in Fig. 3.4, where various possible absorption processes are illustrated. The important features of the behavior of the α versus $h\nu$ can be summarized as follows. (a) Free carrier absorption due to the presence of free electrons and holes, an effect that decreases with increasing photon energy. (b) An impurity absorption band (usually narrow) due to the various dopants. (c) Reststrahlen or lattice absorption in which the radiation is absorbed by vibrations of the crystal ions. (d) Exciton absorption peaks that are usually observed at low temperatures and are close to the fundamental absorption edge. (e) Band-to-band or fundamental absorption of photons, which excites an electron from the valence to the conduction band. Type (e) absorption has a large absorption coefficient and occurs when the photon energy reaches the bandgap energy

Table 3.5 Crystal structure, lattice parameter a , bandgap energy E_g at 300 K, type of bandgap (D=direct and I=indirect), change in E_g per unit temperature change (dE_g/dT) at 300 K, bandgap wavelength λ_g and refractive index n close to λ_g (A=amorphous, D=diamond, W=wurtzite, ZB=zinc blende). Approximate data from various sources

E_g . It is probably the most important absorption effect; its characteristics for $h\nu > E_g$ can be predicted using the results of Sect. 3.3.3. The values of E_g , and its temperature shift, dE_g/dT , are therefore important factors in semiconductor-based optoelectronic devices. In nearly all semiconductors E_g decreases with temperature, hence shifting the fundamental absorption to longer wavelengths. The refractive index n also changes with temperature. dn/dT depends on the wavelength, but for many semiconductors $(dn/dT)/n \approx 5 \times 10^{-5} \text{ K}^{-1}$; for example, for GaAs, $(dn/dT)/n = 4 \times 10^{-4} \text{ K}^{-1}$ at

$\lambda = 2 \mu\text{m}$. There is a good correlation between the refractive indices and the bandgaps of semiconductors in which, typically, n decreases as E_g increases; semiconductors with wider bandgaps have lower refractive indices. The refractive index n and the extinction coefficient K (or α) are related by the Kramers–Kronig relations. Thus, large increases in the absorption coefficient for $h\nu$ near and above the bandgap energy E_g also result in increases in the refractive index n versus $h\nu$ in this region. Optical (and some structural) properties of various semiconductors are listed in Table 3.5.

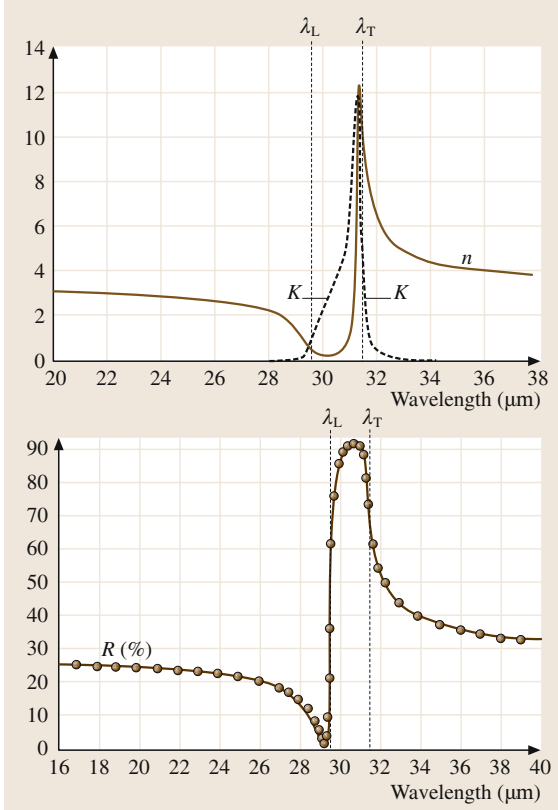

Fig. 3.5 Infrared refractive index n , extinction coefficient K (top), and reflectance R (bottom) of AlSb. Note that the wavelength axes are not identical, and the wavelengths λ_T and λ_L , corresponding to ω_T and ω_L , respectively, are shown as dashed vertical lines. After [3.16]

3.3.1 Lattice or Reststrahlen Absorption and Infrared Reflection

In the infrared wavelength region, ionic crystals reflect and absorb light strongly due to the resonance interaction of the electromagnetic (EM) wave field with the transverse optical (TO) phonons. The dipole oscillator model based on ions driven by an EM wave results in

$$\varepsilon_r = \varepsilon'_r - i\varepsilon''_r = \varepsilon_{r\infty} + \frac{\varepsilon_{r0} - \varepsilon_{r\infty}}{\left(\frac{\omega}{\omega_T}\right)^2 - 1 + i\frac{\gamma}{\omega_T}\left(\frac{\omega}{\omega_T}\right)}, \quad (3.25)$$

where ε_{r0} and $\varepsilon_{r\infty}$ are the relative permittivity at $\omega = 0$ (very low frequencies) and $\omega = \infty$ (very high frequencies) respectively, γ is the loss coefficient per unit reduced mass, representing the rate of energy transfer

from the EM wave to optical phonons, and ω_0 is a resonance frequency that is related to the “spring” constant between the ions. By definition, the frequency ω_T is

$$\omega_T^2 = \omega_0^2 \left(\frac{\varepsilon_{r\infty} + 2}{\varepsilon_{r0} + 2} \right). \quad (3.26)$$

The loss ε''_r and the absorption are maxima when $\omega = \omega_T$, and the wave is attenuated by the transfer of energy to the transverse optical phonons, so the EM wave couples to the transverse optical phonons. At $\omega = \omega_L$, the wave couples to the longitudinal optical (LO) phonons. Figure 3.5 shows the optical properties of AlSb [3.16] in terms of n , K and R versus wavelength. The peaks in the extinction coefficient K and reflectance R occur over roughly the same wavelength region, corresponding to the coupling of the EM wave to the transverse optical phonons. At wavelengths close to $\lambda_T = 2\pi/\omega_T$, n and K peak, and there is strong absorption of light (which corresponds to the EM wave resonating with the TO lattice vibrations), and then R rises sharply.

3.3.2 Free Carrier Absorption (FCA)

An electromagnetic wave with sufficiently low frequency oscillations can interact with free carriers in a material and thereby drift the carriers. This interaction results in an energy loss from the EM wave to the lattice vibrations through the carrier scattering processes. Based on the Drude model, the relative permittivity $\varepsilon_r(\omega)$ due to N free electrons per unit volume is given by

$$\varepsilon_r = \varepsilon'_r - i\varepsilon''_r = 1 - \frac{\omega_p^2}{\omega^2 - i\omega/\tau};$$

$$\omega_p^2 = \frac{Ne^2}{\varepsilon_0 m_e}, \quad (3.27)$$

where ω_p is a plasma frequency which depends on the electron concentration, while τ is the relaxation time of the scattering process (the mean scattering time). For metals where the electron concentration is very large, ω_p is of the order of $\approx 10^{16}$ rad/s, at UV frequencies, and for $\omega > \omega_p$, $\varepsilon_r \approx 1$, and the reflectance becomes very small. Metals lose their free-electron reflectance in the UV range, thus becoming UV-transparent. The reflectance does not fall to zero because there are other absorption processes such as interband electron excitations or excitations from core levels to energy bands. Plasma edge transparency, where the reflectance almost vanishes, can also be observed in doped semiconductors. For example, the reflectance of doped InSb has a plasma edge wavelength that decreases with increasing free carrier concentration [3.17]. Equation (3.27) can be written

Fig. 3.6 Free carrier absorption in n-GaP at 300 K [3.18], p- and n-type PbTe [3.19] at 77 K and In doped n-type ZnO at room temperature. After [3.20]

in terms of the conductivity σ_0 at low frequencies (dc) as

$$\epsilon_r = \epsilon'_r - i\epsilon''_r = 1 - \frac{\tau\sigma_0}{\epsilon_0[(\omega\tau)^2 + 1]} - i\frac{\sigma_0}{\epsilon_0\omega[(\omega\tau)^2 + 1]}. \quad (3.28)$$

In metals, σ_0 is high. At frequencies where $\omega < 1/\tau$, the imaginary part $\epsilon''_r = \sigma_0/\epsilon_0\omega$ is normally much more than 1, and $n = K \approx \sqrt{(\epsilon''_r/2)}$, so that the free carrier attenuation coefficient α is then given by

$$\alpha = 2k_0K \approx \frac{2\omega}{c} \left(\frac{\epsilon''_r}{2} \right)^{1/2} \approx (2\sigma_0\mu_0)^{1/2} \omega^{1/2}. \quad (3.29)$$

Furthermore, the reflectance can also be calculated using $n = K \approx \sqrt{(\epsilon''_r/2)}$, which leads to the well-known Hagen–Rubens relationship [3.21]

$$R \approx 1 - 2 \left(\frac{2\omega\epsilon_0}{\sigma_0} \right)^{1/2}. \quad (3.30)$$

In semiconductors, one typically encounters $\sigma_0/\epsilon_0\omega < 1$, since the free electron concentration is small, and we can treat n as constant due to various other polarization mechanisms such as electronic polarization. Since $2nK = \epsilon''_r$, the absorption coefficient becomes [3.22]:

$$\alpha = 2k_0K \approx \frac{2\omega}{c} \left(\frac{\epsilon''_r}{2n} \right) = \frac{\sigma_0}{nc\epsilon_0[(\omega\tau)^2 + 1]}. \quad (3.31)$$

At low frequencies where $\omega < 1/\tau$, we have $\alpha(\lambda) \propto \sigma_0/n(\lambda)$ so that α should be controlled by the dc conductivity, and hence the amount of doping. Furthermore, α will exhibit the frequency dependence of the refractive index n ($\alpha(\lambda) \propto 1/n(\lambda)$), in which n will typically be determined by the electronic polarization of the crystal.

At high frequencies where $\omega > 1/\tau$,

$$\alpha \propto \sigma_0/\omega^2 \propto N\lambda^2, \quad (3.32)$$

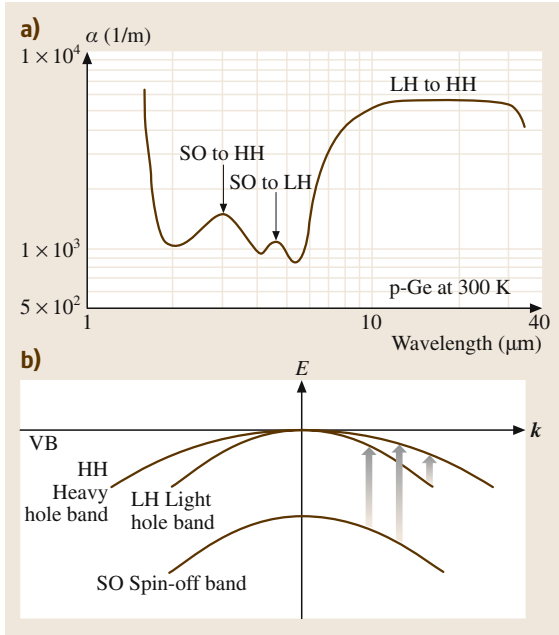

where α is proportional to N , the free carrier concentration, and λ^2 . Experimental observations on FCA in doped semiconductors are in general agreement with these predictions. For example, α increases with N , whether N is increased by doping or by carrier injection [3.23]. However, not all semiconductors show the simple $\alpha \propto \lambda^2$ behavior. A proper account of the field-driven electron motion and scattering must consider the fact that τ will depend on the electron energy. The correct approach is to use the Boltzmann transport equation [3.24] with the appropriate scattering mechanism. FCA can be calculated using a quantum-mechanical approach based on second-order time-dependent perturbation theory with Fermi–Dirac statistics [3.25].

Absorption due to free carriers is commonly written as $\alpha \propto \lambda^p$, where the index p depends primarily on the scattering mechanism, although it is also influenced by the compensation doping ratio, if the semiconductor has been doped by compensation, and the free carrier concentration. In the case of lattice scattering, one must consider scattering from acoustic and optical phonons. For acoustic phonon scattering $p \approx 1.5$, for optical phonon scattering $p \approx 2.5$, and for impurity scattering $p \approx 3.5$. The observed free carrier absorption coefficient will then have all three contributions:

$$\alpha = A_{\text{acoustic}}\lambda^{1.5} + A_{\text{optical}}\lambda^{2.5} + A_{\text{impurity}}\lambda^{3.5}. \quad (3.33)$$

Inasmuch as α for FCA depends on the free carrier concentration N , it is possible to evaluate the latter from the experimentally measured α , given its wavelength dependence and p as discussed by [3.26]. The free carrier absorption coefficients $\alpha(\text{mm}^{-1})$ for GaP, n-type PbTe and n-type ZnO are shown in Fig. 3.6.

Free carrier absorption in p-type Ge demonstrates how the FCA coefficient α can be dramatically different than what is expected from (3.33). Figure 3.7a shows the wavelength dependence of the absorption coefficient for p-Ge over the wavelength range from about 2 to 30 μm [3.27]. The observed absorption is due to excitations of electrons from the spin-off band to the heavy

hole band, from the spin-off band to the light hole band, and from the light hole band to the heavy hole band, as marked in the Fig. 3.7b.

3.3.3 Band-to-Band or Fundamental Absorption

Crystalline Solids

Band-to-band absorption or fundamental absorption of radiation is due to the photoexcitation of an electron from the valence band to the conduction band. There are

Fig. 3.7 (a) Free carrier absorption due to holes in p-Ge [3.27]. (b) The valence band of Ge has three bands; heavy hole, light hole and a spin-off bands

two types of band-to-band absorptions, corresponding to direct and indirect transitions.

A direct transition is a photoexcitation process in which no phonons are involved. The photon momentum is negligible compared with the electron momentum, so that when the photon is absorbed, exciting an electron from the valence band (VB) to the conduction band (CB), the electron's k -vector does not change. A direct transition on an $E-k$ diagram is a vertical transition from an initial energy E and wavevector k in the VB to a final energy E' and a wavevector k' in the CB where $k' = k$, as shown in Fig. 3.8a. The energy $(E' - E_c)$ is the kinetic energy $(\hbar k)^2/(2m_e^*)$ of the electron with an effective mass m_e^* , and $(E_v - E)$ is the kinetic energy $(\hbar k)^2/(2m_h^*)$ of the hole left behind in the VB. The ratio of the kinetic energies of the photogenerated electron and hole depends inversely on the ratio of their effective masses.

The absorption coefficient α is derived from the quantum-mechanical probability of transition from E to E' , the occupied density of states at E in the VB from which electrons are excited, and the unoccupied density of states in the CB at $E + \hbar\nu$. Thus, α depends on the joint density of states at E and $E + \hbar\nu$, and we have to suitably integrate this joint density of states. Near the band edges, the density of states can be approximated by a parabolic band, and α rises with the photon energy following

$$\alpha \hbar\nu = A(\hbar\nu - E_g)^{1/2}, \quad (3.34)$$

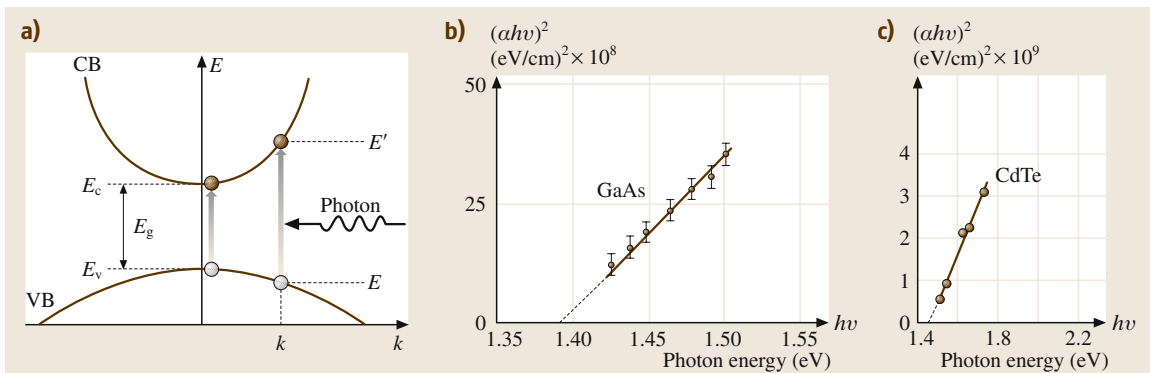

Fig. 3.8 (a) A direct transition from the valence band (VB) to the conduction band (CB) through the absorption of a photon. Absorption behavior represented as $(\alpha \hbar\nu)^2$ versus photon energy $\hbar\nu$ near the band edge for single crystals of (b) p-type GaAs, from [3.28] and (c) CdTe. After [3.29]

where the constant $A \approx [e^2/(nch^2m_e^*)](2\mu^*)^{3/2}$ in which μ^* is a reduced electron and hole effective mass, n is the refractive index, and E_g is the direct bandgap, with minimum $E_c - E_v$ at the same k value. Experiments indeed show this type of behavior for photon energies above E_g and close to E_g , as shown in Fig. 3.8b for a GaAs crystal [3.28] and in (c) for a CdTe crystal [3.29]. The extrapolation to zero photon energy gives the direct bandgap E_g , which is about 1.40 eV for GaAs and 1.46–1.49 eV for CdTe. For photon energies very close to the bandgap energy, the absorption is usually due to exciton absorption, especially at low temperatures, and is discussed later in this chapter.

In indirect bandgap semiconductors, such as Si and Ge, the photon absorption for photon energies near E_g requires the absorption and emission of phonons during the absorption process, as illustrated in Fig. 3.9a. The absorption onset corresponds to a photon energy of $(E_g - h\vartheta)$, which represents the absorption of a phonon with energy $h\vartheta$. For the latter, α is proportional to $[h\nu - (E_g - h\vartheta)]^2$. Once the photon energy reaches $(E_g + h\vartheta)$, then the photon absorption process can also occur by phonon emission, for which the absorption coefficient is larger than that for phonon absorption. The absorption coefficients for the phonon absorption and emission processes are given by [3.30]

$$\alpha_{\text{absorption}} = A[f_{\text{BE}}(h\vartheta)][h\nu - (E_g - h\vartheta)]^2; \quad h\nu > (E_g - h\vartheta), \quad (3.35)$$

and

$$\alpha_{\text{emission}} = A[1 - f_{\text{BE}}(h\vartheta)][h\nu - (E_g + h\vartheta)]^2; \quad h\nu > (E_g + h\vartheta), \quad (3.36)$$

where A is a constant and $f_{\text{BE}}(h\vartheta)$ is the Bose–Einstein distribution function at the phonon energy $h\vartheta$, $f_{\text{BE}}(h\vartheta) = [\exp(h\vartheta/k_B T) - 1]^{-1}$, where k_B is the Boltzmann constant and T is the temperature. As we increase the photon energy in the range $(E_g - h\vartheta) < h\nu < (E_g + h\vartheta)$, the absorption is controlled by $\alpha_{\text{absorption}}$ and the plot of $\alpha^{1/2}$ versus $h\nu$ has an intercept of $(E_g - h\vartheta)$.

On the other hand, for $h\nu > (E_g + h\vartheta)$, the overall absorption coefficient is $\alpha_{\text{absorption}} + \alpha_{\text{emission}}$, but at slightly higher photon energies than $(E_g + h\vartheta)$, α_{emission} quickly dominates over $\alpha_{\text{absorption}}$ since $[f_{\text{BE}}(h\vartheta)] \gg [1 - f_{\text{BE}}(h\vartheta)]$. Figure 3.9b shows the behavior of $\alpha^{1/2}$ versus photon energy for Si at two temperatures for $h\nu$ near band edge absorption. At low temperatures, $f_{\text{BE}}(h\vartheta)$ is small and $\alpha_{\text{absorption}}$ decreases with decreasing temperature, as apparent from Fig. 3.9b.

Equations (3.35) and (3.36) intersect the photon energy axis at $(E_g - h\vartheta)$ and $(E_g + h\vartheta)$, which can be used to obtain E_g .

An examination of the extinction coefficient K or ϵ_r'' versus photon energy for Si in Fig. 3.2 shows that absorption peaks at certain photon energies, $h\nu \approx 3.5$ and 4.3 eV. These peaks are due to the fact that the joint density of states function peaks at these energies. The absorption coefficient peaks whenever there is a direct transition in which the E versus k curve in the VB is parallel to the E versus k curve in the CB, as schematically illustrated in Fig. 3.9a, where a photon of energy $h\nu_{12}$ excites an electron from state 1 in the VB to state 2 in the CB in a direct transition, i.e. $k_1 = k_2$. Such transitions where E versus k curves are parallel at a photon energy $h\nu_{12}$ result in a peak in the absorption versus photon energy behavior, and can be represented by the condition that

$$(\nabla_k E)_{\text{CB}} - (\nabla_k E)_{\text{VB}} = 0. \quad (3.37)$$

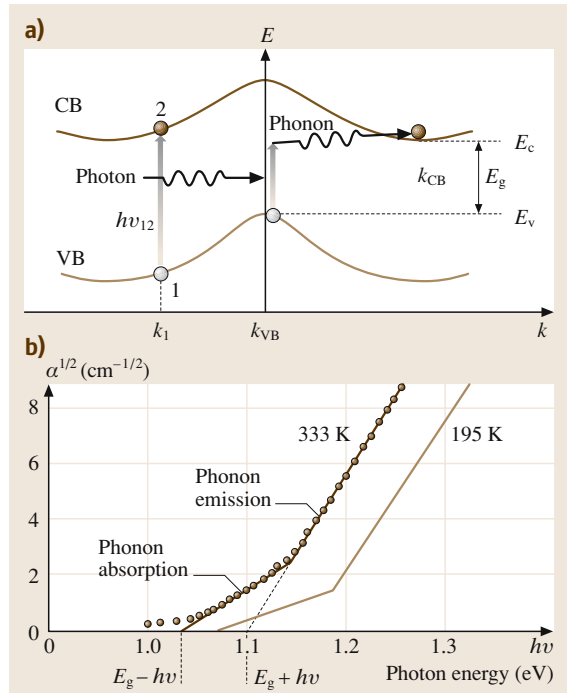

Fig. 3.9 (a) Indirect transitions across the bandgap involve phonons. Direct transitions in which dE/dk in the CB is parallel to dE/dk in the VB lead to peaks in the absorption coefficient. (b) Fundamental absorption in Si at two temperatures. The overall behavior is well described by (3.35) and (3.36)

The above condition is normally interpreted as the joint density of states reaching a peak value at certain points in the Brillouin zone called van Hove singularities. Identification of peaks in K versus $h\nu$ involves the examination of all E versus k curves of a given crystal that can participate in a direct transition. The silicon ε_r'' peaks at $h\nu \approx 3.5$ eV and 4.3 eV correspond to (3.37) being satisfied at points L, along $\langle 111 \rangle$ in k -space, and X along $\langle 100 \rangle$ in k -space, at the edges of the Brillouin zone.

In degenerate semiconductors, the Fermi level E_F is in a band; for example, in the CB for a degenerate n -type semiconductor. Electrons in the VB can only be excited to states above E_F in the CB rather than to the bottom of the CB. The absorption coefficient then depends on the free carrier concentration since the latter determines E_F . Fundamental absorption is then said to depend on band filling, and there is an apparent shift in the absorption edge, called the *Burstein–Moss shift*. Furthermore, in degenerate indirect semiconductors, the indirect transition may involve a non-phonon scattering process, such as impurity or electron–electron scattering, which can change the electron’s wavevector k . Thus, in degenerate indirect bandgap semiconductors, absorption can occur without phonon assistance and the absorption coefficient becomes:

$$\alpha \propto [h\nu - (E_g + \Delta E_F)]^2, \quad (3.38)$$

where ΔE_F is the energy depth of E_F into the band measured from the band edge.

Heavy doping of degenerate semiconductors normally leads to a phenomenon called bandgap narrowing and bandtailing. Bandtailing means that the band edges at E_v and E_c are no longer well defined cut-off energies, and there are electronic states above E_v and below E_c where the density of states falls sharply with energy away from the band edges. Consider a degenerate direct band gap p -type semiconductor. One can excite electrons from states below E_F in the VB, where the band is nearly parabolic, to tail states below E_c , where the density of states decreases exponentially with energy into the bandgap, away from E_c . Such excitations lead to α depending exponentially on $h\nu$, a dependence that is called the *Urbach rule* [3.31, 32], given by:

$$\alpha = \alpha_0 \exp[(h\nu - E_0)/\Delta E] \quad (3.39)$$

where α_0 and E_0 are material-dependent constants, and ΔE , called the Urbach width, is also a material-dependent constant. The Urbach rule was originally reported for alkali halides. It has been observed for many

ionic crystals, degenerately doped crystalline semiconductors, and almost all amorphous semiconductors. While exponential bandtailing can explain the observed Urbach tail of the absorption coefficient versus photon energy, it is also possible to attribute the absorption tail behavior to strong internal fields arising, for example, from ionized dopants or defects.

Amorphous Solids

In a defect-free crystalline semiconductor, a well-defined energy gap exists between the valence and conduction bands. In contrast, in an amorphous semiconductor, the distributions of conduction band and valence band electronic states do not terminate abruptly at the band edges. Instead, some electronic states called the tail states encroach into the gap region [3.33]. In addition to tail states, there are also other localized states deep within the gap region [3.34]. These localized tail states in amorphous semiconductors are contributed by defects. The defects in amorphous semiconductors are considered to be all cases of departure from the normal nearest-neighbor coordination (or normal valence requirement). Examples of defects are: broken and dangling bonds (typical for amorphous silicon), over- and under-coordinated atoms (such as “valence alternation pairs” in chalcogenide glasses), voids, pores, cracks and other macroscopic defects. Mobility edges exist, which separate these localized states from their extended counterparts; tail and deep defect states are localized [3.35–37]. These localized tail and deep defect states are responsible for many of the unique properties exhibited by amorphous semiconductors.

Despite years of intensive investigation, the exact form of the distribution of electronic states associated with amorphous semiconductors remains a subject of some debate. While there are still some unresolved theoretical issues, there is general consensus that the tail states arise as a consequence of the disorder present within amorphous networks, and that the width of these tails reflects the amount of disorder present [3.38]. Experimental results (from, for example, [3.39, 40]) suggest exponential distributions for the valence and conduction band tail states in a-Si:H, although other possible functional forms [3.41] cannot be ruled out. Singh and Shimakawa [3.37] have derived separate effective masses of charge carriers in their extended and tail states. That means the density of states (DOS) of extended and tail states can be represented in two different parabolic forms. The relationship between the absorption coefficient and the distribution of electronic states for the case of a-Si:H may be found in [3.37, 42–44].

The existence of tail states in amorphous solids has a profound impact upon the band-to-band optical absorption. Unlike in a crystalline solid, the absorption of photons in an intrinsic amorphous solid can also occur for photon energies $\hbar\omega \leq E_0$ due to the presence of tail states in the forbidden gap. E_0 is the energy of the optical gap, which is usually close to the mobility gap – the energy difference between the conduction band and valence band mobility edges.

In a crystalline semiconductor, the energy and crystal momentum of an electron involved in an optical transition must be conserved. In an amorphous semiconductor, however, only the energy needs to be conserved [3.36, 37]. As a result, for optical transitions caused by photons of energy $\hbar\omega \geq E_0$ in amorphous semiconductors, the approach of a joint density of states is not applicable [3.37, 45]. One has to consider the product of the densities of both conduction and valence electronic states when calculating the absorption coefficient [3.37, 46]. Assuming that both the valence band and conduction band DOS functions have square-root dependencies on energy, one can derive the absorption coefficient α as [3.37]:

$$(\alpha\hbar\omega)^{1/2} = B^{1/2}(\hbar\omega - E_0), \quad (3.40)$$

where, if one assumes that the transition matrix element is constant,

$$B = \frac{1}{nc\epsilon_0} \left(\frac{e}{m_e^*} \right)^2 \left(\frac{L(m_e^*m_h^*)^{3/2}}{2^2\hbar^3} \right) \quad (3.41)$$

where m_e^* and m_h^* are the effective masses of an electron and a hole, respectively, L denotes the average interatomic separation in the sample, and n is the refractive index. Plotting $(\alpha\hbar\omega)^{1/2}$ as a function of $\hbar\omega$ yields a straight line that is usually referred to as Tauc's plot, from which one can determine the optical gap energy E_0 experimentally. Equation (3.40) is also known as Tauc's relation and B as Tauc's constant [3.47]. Experimental data from many, but not all, amorphous semiconductors and chalcogenides fit to (3.40) very well. Deviations from Tauc's relation have been observed. For instance, some experimental data in a-Si:H fit much better to a cubic root relation given by *Mott and Davis* [3.36]:

$$(\alpha\hbar\omega)^{1/3} = C(\hbar\omega - E_0) \quad (3.42)$$

and therefore the cubic root has been used to determine the optical gap E_0 . Here C is another constant.

If one considers that the optical transition matrix element is independent of photon energy [3.37, 48], one finds that the cubic root dependence on photon energy

can be obtained only when the valence band and conduction band DOS depend linearly on energy. Using such DOS functions, the cubic root dependence has been explained by *Mott and Davis* [3.36]. Another way to obtain the cubic root dependence has been suggested in [3.49]. Using (3.40), *Sokolov et al.* [3.49] have modeled the cubic root dependence on photon energy by considering the fluctuations in the optical band gap due to structural disorder. Although their approach gives a way of getting the cubic root dependence, *Sokolov et al.*'s model is hardly different from the linear density of states model suggested by *Mott and Davis* [3.36]. *Cody* [3.50] has shown an alternative approach using a photon energy-dependent transition matrix element. Thus, the absorption coefficient is obtained as [3.37]:

$$(\alpha\hbar\omega) = B'(\hbar\omega)^2(\hbar\omega - E_0)^2, \quad (3.43)$$

where

$$B' = \frac{e^2}{nc\epsilon_0} \left(\frac{(m_e^*m_h^*)^{3/2}}{2\pi^2\hbar^7\nu\rho_A} \right) Q_a^2, \quad (3.44)$$

and Q_a is the average separation between the excited electron and hole pair in an amorphous semiconductor, ν denotes the number of valence electrons per atom and ρ_A represents the atomic density per unit volume.

Equation (3.43) suggests that $(\alpha\hbar\omega)$ depends on the photon energy in the form of a polynomial of order 4. Then, depending on which term of the polynomial may be more significant in which material, one can get square, cubic or fourth root dependences of $(\alpha\hbar\omega)$ on

Fig. 3.10 Schematic illustration of the electronic energy states E_2 , E_c , E_{ct} , E_{vt} , E_v and E_{v2} in amorphous semiconductors. The shaded region represents the extended states. Energies E_2 and E_{v2} correspond to the centers of the conduction and valence extended states and E_{ct} and E_{vt} represent the ends of the conduction and valence tail states, respectively

the photon energy. In this case, (3.43) may be expressed as:

$$(\alpha\hbar\omega)^x \propto (\hbar\omega - E_0), \quad (3.45)$$

where $x \leq 1/2$. Thus, in a way, any deviation from the square root or Tauc's plot may be attributed to the energy-dependent matrix element [3.37, 46]. Another possible explanation has been recently discussed by Shimakawa and coworkers on the base of fractal theory [3.54].

Another problem is how to determine the constants B (3.41) and B' (3.44), which involve the effective masses of an electron and a hole. In other words, how do we determine the effective masses of charge carriers in amorphous solids? Recently, a simple approach [3.37, 46] has been developed to calculate the effective masses of charge carriers in amorphous solids. Different effective masses of charge carriers are obtained in the extended and tail states. The approach applies the concepts of tunneling and effective medium, and one obtains the effective mass of an electron in the conduction extended states, denoted by m_{ex}^* , and in the tail states, denoted by m_{et}^* , as:

$$m_{\text{ex}}^* \approx \frac{E_L}{2(E_2 - E_c)a^{1/3}} m_e, \quad (3.46)$$

and

$$m_{\text{et}}^* \approx \frac{E_L}{(E_c - E_{\text{ct}})b^{1/3}} m_e, \quad (3.47)$$

where:

$$E_L = \frac{\hbar^2}{m_e L^2}. \quad (3.48)$$

Here $a = \frac{N_1}{N} < 1$, N_1 is the number of atoms contributing to the extended states, $b = \frac{N_2}{N} < 1$, N_2 is the number of atoms contributing to the tail states, such that $a + b = 1$ ($N = N_1 + N_2$), and m_e is the free electron mass. The energy E_2 in (3.46) corresponds to the energy of the middle of the extended conduction states, at which the imaginary part of the dielectric constant becomes maximum (Fig. 3.10; see also Fig. 3.2).

Likewise, the effective masses of the hole m_{hx}^* and m_{ht}^* in the valence extended and tail states are obtained, respectively, as:

$$m_{\text{hx}}^* \approx \frac{E_L}{2(E_v - E_{v2})a^{1/3}} m_e, \quad (3.49)$$

and

$$m_{\text{ht}}^* \approx \frac{E_L}{(E_{vt} - E_v)b^{1/3}} m_e, \quad (3.50)$$

where E_{v2} and E_{vt} are energies corresponding to the half-width of the valence extended states and the end of the valence tail states, respectively; see Fig. 3.10.

Using (3.46) and (3.47) and the values of the parameters involved, different effective masses of an electron are obtained in the extended and tail states. Taking, for example, the density of weak bonds contributing to the tail states as 1 at. %, so $b = 0.01$ and $a = 0.99$, the effective masses and energies E_L calculated for hydrogenated amorphous silicon (a-Si:H) and germanium (a-Ge:H) are given in Table 3.6.

According to (3.46), (3.47), (3.49) and (3.50), for sp^3 hybrid amorphous semiconductors such as a-Si:H and a-Ge:H, effective masses of the electron and hole are expected to be the same. In these semiconductors, since the conduction and valence bands are two equal halves of the same electronic band, their widths are the same and that gives equal effective masses for the electron and the hole [3.37, 55]. This is one of the reasons for using $E_{\text{ct}} = E_{\text{vt}} = E_c/2$, which gives equal effective masses for electrons and holes in the tail states as well. This is different from crystalline solids where m_e^* and m_h^* are usually not the same. This difference between amorphous and crystalline solids is similar to, for example, having direct and indirect crystalline semiconductors but only direct amorphous semiconductors.

Using the effective masses from Table 3.6 and (3.41), B can be calculated for a-Si:H and a-Ge:H. The values thus obtained with the refractive index $n = 4$ for a-Si:H and a-Ge:H are $B = 6.0 \times 10^6 \text{ cm}^{-1} \text{ eV}^{-1}$ for a-Si:H and $B = 4.1 \times 10^6 \text{ cm}^{-1} \text{ eV}^{-1}$ for a-Ge:H, which are an order of magnitude higher than those estimated from

Table 3.6 Effective mass of electrons in the extended and tail states of a-Si:H and a-Ge:H calculated using Eqs. (3.46) and (3.47) for $a = 0.99$, $b = 0.01$ and $E_{\text{ct}} = E_{\text{vt}} = E_c/2$. E_L is calculated from (3.48). All energies are given in eV. Note that since the absorption coefficient is measured in cm^{-1} , the value used for the speed of light is in cm/s (a [3.51]; b [3.52]; c [3.33]; d [3.53])

	$L(\text{nm})$	E_2	E_c	E_L	$E_c - E_{\text{ct}}$	m_{ex}^*	m_{et}^*
a-Si:H	0.235 ^a	3.6 ^b	1.80 ^c	1.23	0.9	$0.34m_e$	$6.3m_e$
a-Ge:H	0.245 ^a	3.6	1.05 ^d	1.14	0.53	$0.22m_e$	$10.0m_e$

experiments [3.36]. However, considering the quantities involved in B (3.41), this can be regarded as a reasonable agreement.

In a recent paper, *Malik and O'Leary* [3.56] studied the distributions of conduction and valence band electronic states associated with a-Si:H. They noted that the effective masses associated with a-Si:H are material parameters that are yet to be experimentally determined. In order to remedy this deficiency, they fitted square-root DOS functions to experimental DOS data and found that $m_h^* = 2.34m_e$ and $m_e^* = 2.78m_e$.

The value of the constant B' in (3.44) can also be calculated theoretically, provided that Q_a is known. Using the atomic density of crystalline silicon and four valence electrons per atom, *Cody* [3.50] estimated $Q_a^2 = 0.9 \text{ \AA}^2$, which gives $Q_a \approx 0.095 \text{ nm}$, less than half the interatomic separation of 0.235 nm in a-Si:H, but of the same order of magnitude. Using $\nu = 4$, $\rho_A = 5 \times 10^{28} \text{ m}^{-3}$, $Q_a^2 = 0.9 \text{ \AA}^2$, and extended state effective masses, we get $B' = 4.6 \times 10^3 \text{ cm}^{-1} \text{ eV}^{-3}$ for a-Si:H and $1.3 \times 10^3 \text{ cm}^{-1} \text{ eV}^{-3}$ for a-Ge:H. *Cody* estimated an optical gap, $E_0 = 1.64 \text{ eV}$, for a-Si:H, which, using in (3.43), gives $\alpha = 1.2 \times 10^3 \text{ cm}^{-1}$ at a photon energy of $\hbar\omega = 2 \text{ eV}$. This agrees reasonably well with the $\alpha = 6.0 \times 10^2 \text{ cm}^{-1}$ used by *Cody*. If we use interatomic spacing in place of Q_a in (3.44), we get $B' = 2.8 \times 10^4 \text{ cm}^{-1} \text{ eV}^{-3}$, and then the corresponding

absorption coefficient becomes $3.3 \times 10^3 \text{ cm}^{-1}$. This suggests that, in order to get an estimate, one may use the interatomic spacing in place of Q_a if the latter is unknown. Thus, both B and B' can be determined theoretically, a task not possible before due to a lack of knowledge of the effective masses in amorphous semiconductors.

The absorption of photons of energy less than the band gap energy, $\hbar\omega < E_0$ in amorphous solids involves the localized tail states and hence follows neither (3.40) nor (3.42). Instead, the absorption coefficient depends on the photon energy exponentially, as given in (3.39), giving rise to Urbach's tail. *Abe and Toyozawa* [3.57] have calculated the interband absorption spectra in crystalline solids, introducing the Gaussian site diagonal disorder and applying the coherent potential approximation. They have shown that Urbach's tail occurs due to static disorder (structural disorder). However, the current stage of understanding is that Urbach's tail in amorphous solids occurs due to both thermal effects and static disorder [3.50]. More recent issues in this area have been addressed by *Orapunt and O'Leary* [3.48].

Keeping the above discussion in mind, the optical absorption in amorphous semiconductors near the absorption edge is usually characterized by three types of optical transitions corresponding to transitions between tail and tail states, tail and extended states, and extended and extended states. The first two types correspond to $\hbar\omega \leq E_0$, and the third one corresponds to $\hbar\omega \geq E_0$. Thus, the plot of absorption coefficient versus photon energy (α versus $\hbar\omega$) has three different regions, A, B and C, respectively, that correspond to these three characteristic optical transitions shown in Fig. 3.11.

In the small absorption coefficient range A (also called the weak absorption tail, WAT), where $\alpha < 10^{-1} \text{ cm}^{-1}$, the absorption is controlled by optical transitions from tail-to-tail states. As stated above, the localized tail states in amorphous semiconductors are contributed by defects. To some extent, the absolute value of absorption in region A may be used to estimate the density of defects in the material. In region B, where typically $10^{-1} < \alpha < 10^4 \text{ cm}^{-1}$, the absorption is related to transitions from the localized tail states above the valence band edge to extended states in the conduction band and/or from extended states in the valence band to localized tail states below the conduction band. The spectral dependence of α usually follows the so-called Urbach rule, given in (3.39). For many amorphous semiconductors, ΔE has been related to the width of the valence (or conduction) band tail states, and may be used to compare the “widths” of such localized tail states in

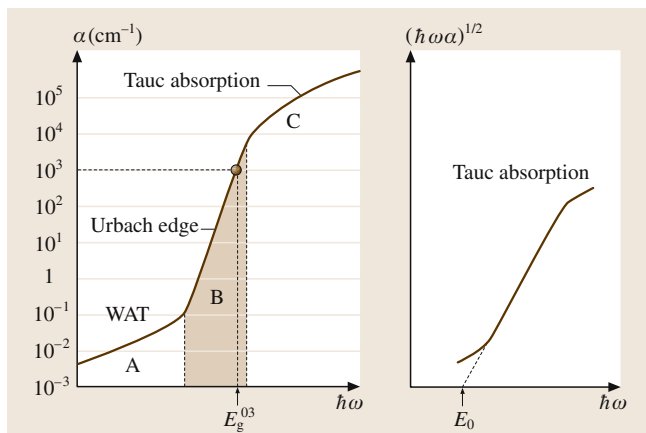

Fig. 3.11 Typical spectral dependence of the optical absorption coefficient in amorphous semiconductors. In the A and B regions, the absorption is controlled by optical transitions between tail and tail states and tail and extended states, respectively, and in the C region it is dominated by transitions from extended to extended states. In domain B, the absorption coefficient follows the Urbach rule (3.39). In region C, the absorption coefficient follows Tauc's relation (3.40) in a-Si:H, as shown in the figure on the right-hand side

Table 3.7 Optical bandgaps of a-Si_{1-x}C_x:H films obtained from Tauc's (3.40), Sokolov et al.'s (3.42) and Cody's (3.43) relations [3.58]

	E_g at $\alpha = 10^3 \text{ cm}^{-1}$	E_g at $\alpha = 10^4 \text{ cm}^{-1}$	$E_g = E_0$ (Tauc)	$E_g = E_0$ (Cody)	$E_g = E_0$ (Sokolov)	ΔE (meV)
a-Si:H	1.76	1.96	1.73	1.68	1.60	46
a-Si _{0.88} C _{0.18} :H	2.02	2.27	2.07	2.03	1.86	89

different materials; ΔE is typically 0.05–0.1 eV. In region C, the absorption is controlled by transitions from extended to extended states. For many amorphous semiconductors, the α versus $\hbar\omega$ behavior follows the Tauc relation given in (3.40). The optical bandgap, E_0 , determined for a given material from the α versus $\hbar\omega$ relations obtained in (3.40), (3.42) and (3.43), can vary as shown in Table 3.7 for a-Si:H alloys.

3.3.4 Exciton Absorption

Excitons in Crystalline Semiconductors

Optical absorption in crystalline semiconductors and insulators can create an exciton, which is an electron and hole pair excited by a photon and bound together through their attractive Coulomb interaction. This means that the absorbed optical energy remains held within the solid for the lifetime of the exciton. There are two types of excitons that can be formed in nonmetallic solids: Wannier or Wannier–Mott excitons and Frenkel excitons. The concept of Wannier–Mott excitons is valid for inorganic semiconductors like Si, Ge and GaAs, because in these materials the large overlap of interatomic electronic wavefunctions enables the electrons and holes to be far apart but bound in an excitonic state. For this reason, these excitons are also called large-radii orbital excitons. Excitons formed in organic crystals are called Frenkel excitons. In organic semiconductors/insulators or molecular crystals, the intermolecular separation is large and hence the overlap of intermolecular electronic wavefunctions is very small and electrons remain tightly bound to individual molecules. Therefore, the electronic energy bands are very narrow and closely related to individual molecular electronic energy levels. In these solids, the absorption of photons occurs close to the individual molecular electronic states and excitons are also formed within the molecular energy levels (see [3.59]). Such excitons are therefore also called molecular excitons. For a more detailed look at the theory of Wannier and Frenkel excitons, readers may like to refer to Singh [3.59].

In Wannier–Mott excitons, the Coulomb interaction between the hole and electron can be viewed as an

effective hydrogen atom with, for example, the hole establishing the coordinate reference frame about which the reduced mass electron moves. If the effective masses of the isolated electron and hole are m_e^* and m_h^* , respectively, their reduced mass μ_x is given by:

$$\mu_x^{-1} = (m_e^*)^{-1} + (m_h^*)^{-1}. \quad (3.51)$$

Note that in the case of so-called hydrogenic impurities in semiconductors (both shallow donor and acceptor impurities), the reduced mass of the nucleus takes the place of one of the terms in (3.51) and hence the reduced mass is given to good approximation by the effective mass of the appropriate carrier. When the exciton is the carrier, the effective masses are comparable and hence the reduced mass is markedly lower; accordingly, the exciton binding energy is markedly lower than that for hydrogenic impurities. The energy of a Wannier–Mott exciton is given by (e.g. [3.59]):

$$E_x = E_g + \frac{\hbar^2 K^2}{2M} - E_n, \quad (3.52)$$

where E_g is the band gap energy, $\hbar K$ is the linear momentum, $M (= m_e^* + m_h^*)$ is the effective mass associated with the center of mass of an exciton, and E_n is the exciton binding energy given by

$$E_n = \frac{\mu_x e^4 \kappa^2}{2\hbar^2 \epsilon^2} \frac{1}{n^2} = \frac{R_y^x}{n^2}, \quad (3.53)$$

where e is the electronic charge, $\kappa = \frac{1}{4\pi\epsilon_0}$, ϵ is the static dielectric constant of the solid, and n is the principal quantum number associated with the internal excitonic states $n = 1(s), 2(p), \dots$ (see Fig. 3.12). According to (3.53), the excitonic states are formed within the band gap below the conduction band edge. However, as the exciton binding energy is very small (a few meV in bulk Si and Ge crystals), exciton absorption peaks can only be observed at very low temperatures. R_y^x is the so-called effective Rydberg of the exciton given by $R_y(\mu_x/m_e)/\epsilon^2$, where $R_y = 13.6 \text{ eV}$. For bulk GaAs, the exciton binding energy ($n = 1$) corresponds to about 5 meV. Extrapolating from the hydrogen atom model, the extension of the excitonic wavefunction can be found from an effective Bohr radius a_B^* given in terms of the Bohr radius

Fig. 3.12 Schematic illustration of excitonic bands for $n = 1$ and 2 in semiconductors. E_g represents the energy gap

as $a_B = \hbar^2/\pi e^2$; that is, $a_B^* = a_B(\epsilon/\mu_x)$. For GaAs this corresponds to about 12 nm or about 21 lattice constants – in other words the spherical volume of the exciton radius contains $\approx (a_B^*/a_0)^3$ or ≈ 9000 unit cells, where a_0 is the lattice constant of GaAs. As $Ry^* \ll E_g$ and $a_B^* \gg a_0$, it is clear from this example that the excitons in GaAs are large-radii orbital excitons, as stated above. It should be noted that the binding energies of excitons in semiconductors tend to be a strong function of the bandgap. The dependencies of R_y^x (exciton binding energy) and a_B^*/a_0 on the semiconductor bandgap are shown in Fig. 3.13a and b, respectively. For excitons with large binding energies and correspondingly small radii (approaching the size of a lattice parameter), the excitons become localized on a lattice site, as observed in most organic semiconductors. As stated above, such excitons are commonly referred to as Frenkel excitons or molecular excitons. Unlike Wannier-based excitons which are typically dissociated at room temperature, these excitations are stable at room temperature. For the binding energies of Frenkel excitons, one can refer to Singh for example [3.59].

Excitons can recombine radiatively, emitting a series of hydrogen-like spectral lines, as described by (3.52). In bulk (3-D) semiconductors such as GaAs, exciton lines can only be observed at low temperatures: they are easily dissociated by thermal fluctuations. On the other hand, in quantum wells and other structures of reduced dimensionality, the spatial confinement of both the electron and hole wavefunctions in the same layer ensures strong excitonic transitions of a few meV be-

low the bandgap, even at room temperature. Excitonic absorption is well-located spectrally and very sensitive to optical saturation. For this reason, it plays an important role in nonlinear semiconductor devices (nonlinear Fabry–Perot resonators, nonlinear mirrors, saturable absorbers, and so on). If the valence hole is a heavy hole, the exciton is called a heavy exciton; conversely, if the valence hole is light, the exciton is a light exciton. For practical purposes, the excitonic contribution to the overall susceptibility around the resonance frequency ν_{ex} can be written as:

$$\chi_{exc} = -A_0 \frac{(\nu - \nu_{ex}) + i\Gamma_{ex}}{(\nu - \nu_{ex})^2 + \Gamma_{ex}^2(1 + S)}, \quad (3.54)$$

where Γ_{ex} is the linewidth and $S = I/I_S$ the saturation parameter of the transition. For instance, in GaAs MQW, the saturation intensity I_S is as low as 1 kW/cm², and Γ_{ex} (≈ 3.55 meV at room temperature) varies with the temperature according to

$$\Gamma_{ex} = \Gamma_0 + \frac{\Gamma_1}{\exp(\hbar\omega_{LO}/kT) - 1}, \quad (3.55)$$

where $\hbar\Gamma_0$ is the inhomogeneous broadening (≈ 2 meV), $\hbar\Gamma_1$ is the homogeneous broadening (≈ 5 meV), and

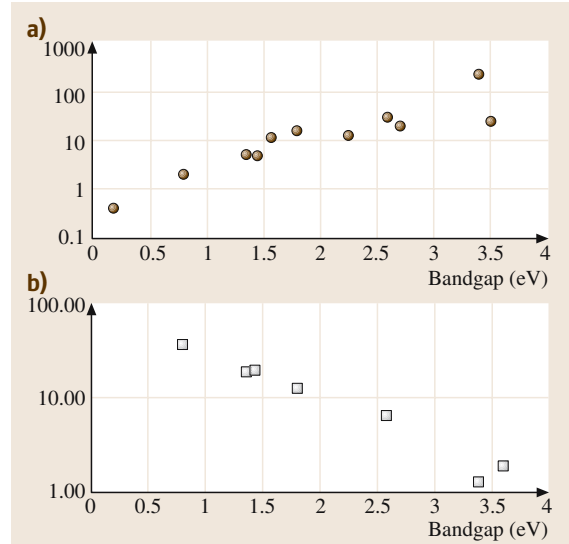

Fig. 3.13a,b Dependence of the (a) exciton binding energy (R_y^x) (3.29) and (b) size (in terms of the ratio of the excitonic Bohr radius to lattice constant (a_B^*/a_0)) as a function of the semiconductor bandgap. Exciton binding energy increases along with a marked drop in exciton spreading as bandgap increases. The Wannier-based description is not appropriate above a bandgap of about 2 eV

$\hbar\omega_{\text{LO}}$ is the longitudinal optical phonon energy (≈ 36 meV). At high carrier concentrations (provided either by electrical pumping or by optical injection), the screening of the Coulomb attractive potential by free electrons and holes provides an efficient mechanism for saturating the excitonic line.

The above discussion refers to so-called free excitons formed between conduction band electrons and valence band holes. According to (3.52), such an excitation is able to move throughout a material with a given center-of-mass kinetic energy (second term on the right hand side). It should be noted, however, that free electrons and holes move with a velocity $\hbar(dE/dk)$ where the derivative is taken for the appropriate band edge. To move through a crystal, both the electron and the hole must have identical translational velocities, restricting the regions in k -space where these excitations can occur to those with $(dE/dk)_{\text{electron}} = (dE/dk)_{\text{hole}}$, commonly referred to as critical points.

A number of more complex pairings of carriers can also occur, which may also include fixed charges or ions. For example, for the case of three charged entities with one being an ionized donor impurity (D+), the following possibilities can occur: (D+)(+)(-), (D+)(-)(-) and (+)(+)(-) as excitonic ions, and (+)(+)(-)(-) and (D+)(+)(-)(-) as biexcitons or even bigger excitonic molecules (see [3.60]). Complexity abounds in these systems, as each electronic level possesses a fine structure corresponding to allowed rotational and vibrational levels. Moreover, the effective mass is often anisotropic. Note that when the exciton or exciton complex is bound to a fixed charge, such as an ionized donor or acceptor center in the material, the exciton or exciton complex is referred to as a bound exciton. Indeed, bound excitons may also involve neutral fixed impurities. It is usual to relate the exciton in these cases to the center binding them; thus, if an exciton is bound to a donor impurity, it is usually termed a donor-bound exciton.

Excitons in Amorphous Semiconductors

The concept of excitons is traditionally valid only for crystalline solids. However, several observations in the photoluminescence spectra of amorphous semiconductors have revealed the occurrence of photoluminescence associated with singlet and triplet excitons [3.37]. Applying the effective mass approach, a theory for the Wannier–Mott excitons in amorphous semiconductors has recently been developed in real coordinate space [3.37, 46, 55, 61]. The energy of an exciton thus

derived is obtained as:

$$W_x = E_0 + \frac{P^2}{2M} - E_n(S), \quad (3.56)$$

where P is the linear momentum associated with the exciton's center of motion and $E_n(S)$ is the binding energy of the exciton, given by

$$E_n(S) = \frac{\mu_x e^4 \kappa^2}{2\hbar^2 \varepsilon'(S)^2 n^2}, \quad (3.57)$$

where

$$\varepsilon'(S) = \varepsilon \left[1 - \frac{(1-S)}{A} \right]^{-1}, \quad (3.58)$$

where S is the spin (S being = 0 for singlet and = 1 for triplet) of an exciton and A is a material-dependent constant representing the ratio of the magnitude of the Coulomb and exchange interactions between the electron and the hole of an exciton. Equation (3.57) is analogous to (3.53) obtained for excitons in crystalline solids for $S = 1$. This is because (3.53) is derived within the large-radii orbital approximation, which neglects the exchange interaction and hence is valid only for triplet excitons [3.59, 62]. As amorphous solids lack long-range order, the exciton binding energy is found to be larger in amorphous solids than in their crystalline counterparts; for example, the binding energy is higher in hydrogenated amorphous silicon (a-Si:H) than in crystalline silicon (c-Si). This is the reason that it is possible to observe both singlet and triplet excitons in a-Si:H [3.63] but not in c-Si.

Excitonic Absorption

Since exciton states lie below the edge of the conduction band in a crystalline solid, absorption to excitonic states is observed below this edge. According to (3.53), the difference in energy in the bandgap and the excitonic absorption gives the binding energy. As the exciton–photon interaction operator and excited electron and hole pair and photon interaction operator depend only on their relative motion, these interactions take the same form for band-to-band and excitonic absorption. Therefore, to calculate the excitonic absorption coefficient, one can use the same form of interaction as that used for band-to-band absorption, but one must use the joint density of states. Using the joint density of states, the absorption coefficient associated with the excitonic states in crystalline semiconductors is obtained as ([3.37]):

$$\alpha \hbar\omega = A_x (\hbar\omega - E_x)^{1/2} \quad (3.59)$$

with the constant $A_x = 4\sqrt{2} e^2 |p_{xv}|^2 / nc \sqrt{\mu_x} \hbar^2$, where p_{xv} is the transition matrix element between the valence and excitonic bands. Equation (3.59) is similar to that seen for direct band-to-band transitions, discussed above ((3.60)), and is only valid for the photon energies $\hbar\omega \geq E_x$. There is no absorption below the excitonic ground state in pure crystalline solids. Absorption of photons to excitonic energy levels is possible through either the excitation of electrons to higher energy levels in the conduction band and then nonradiative relaxation to the excitonic energy level, or through the excitation of an electron directly to the exciton energy level. Excitonic absorption occurs in both direct and indirect semiconductors.

In amorphous semiconductors, the excitonic absorption and photoluminescence can be quite complicated. According to (3.56), the excitonic energy level is below the optical band gap by an energy equal to the binding energy given in (3.57). However, there are four transition possibilities: (i) extended valence to extended conduction states, (ii) valence to extended conduction states, (iii) valence extended to conduction tail states, and (iv) valence tail to conduction tail states. These possibilities will have different optical gap energies, E_0 , and different binding energies. Transition (i) will give rise to absorption in the free exciton states, transitions (ii) and (iii) will give absorption in the bound exciton states, because one of the charge carriers is localized in the tail states, and absorption through transition (iv) will create localized excitons, which are also called geminate pairs. This can be visualized as follows: if an electron–hole pair is excited by a high-energy photon through transition (i) and forms an exciton, initially its excitonic energy level and the corresponding Bohr radius will have a reduced mass corresponding to both charge carriers being in extended states. As such an exciton relaxes downward nonradiatively, its binding energy and excitonic Bohr radius will change because its effective mass changes in the tail states. When both charge carriers reach the tail

Fig. 3.14 Energy level diagram of the low-lying $4f^N$ states of trivalent ions doped in LaCl_3 . After [3.64–66]. The pendant semicircles indicate fluorescent levels ►

states (transition (iv)), their excitonic Bohr radius will be maintained although they are localized.

The excitonic absorption coefficient in amorphous semiconductors can be calculated using the same approach as presented in Sect. 3.3.3, and similar expressions to (3.40) and (3.43) are obtained. This is because the concept of the joint density of states is not applicable in amorphous solids. Therefore, by replacing the effective masses of the charge carriers by the excitonic reduced mass and the distance between the excited electron and hole by the excitonic Bohr radius, one can use (3.40) and (3.43) to calculate the excitonic absorption coefficients for the four possible transitions above in amorphous semiconductors. However, such a detailed calculation of the excitonic transitions in amorphous semiconductors is yet to be performed.

3.3.5 Impurity Absorption

Impurity absorption can be observed as the absorption coefficient peaks lying below fundamental (band-to-band) and excitonic absorption. It is usually related to the presence of ionized impurities or, simply, ions. The peaks occur due to electronic transitions between ionic electronic states and the conduction/valence band or due to intra-ionic transitions (within d or f shells, between s and d shells, and so on). The first case leads to intense and broad lines, while the characteristics of the features arising from the latter case depend on whether or not these transitions are allowed by parity selection rules. For allowed transitions, the absorption peaks are quite intense and broad, while forbidden transitions produce weak and narrow peaks. General reviews of this topic may be found in *Blasse* and *Grabmaier* [3.67], *Hen-*

dereson and Imbusch [3.65] and DiBartolo [3.68]. In the following section, we concentrate primarily on the properties of rare earth ions, which are of great importance in modern optoelectronics.

Optical Absorption of Trivalent Rare Earth Ions: Judd–Ofelt Analysis

Rare earths (REs) is the common name used for the elements from Lanthanum (La) to Lutetium (Lu). They have atomic numbers of 57 to 71 and form a separate group in Periodic Table. The most notable feature of these elements is an incompletely filled 4f shell. The electronic configurations of REs are listed in Table 3.8. The RE may be embedded in different host materials in the form of divalent or trivalent ions. As divalent ions, REs exhibit broad absorption–emission lines related to allowed 4f→5d transitions. In trivalent form, REs lose two 6s electrons and one 4f or 5d electron. The Coulomb interaction of a 4f electron with a positively charged core means that the 4f level gets split into complicated set of manifolds with energies, to a first approximation, that are virtually independent of the host matrix because the 4f level is well screened from external influences by the 5s and 5p shells [3.69]. The Fig. 3.14 shows an energy level diagram for the low-lying 4f^N states of the trivalent ions embedded in LaCl₃. To a second approximation, the exact construction and precise energies of the manifolds depend on the host material, via crystal field and via covalent interactions with the ligands surrounding the RE ion. A ligand is an atom (or molecule or radical or ion) with one or more unshared pairs of electrons that can attach to a central metallic ion (or atom) to form a coordination complex. Examples of ligands include ions (F[−], Cl[−], Br[−], I[−], S^{2−}, CN[−], NCS[−], OH[−], NH₂[−]) and molecules (NH₃, H₂O, NO, CO) that donate a pair of electrons to a metal atom or ion. Some ligands that share electrons with metals form very stable complexes.

Optical transitions between 4f manifold levels are forbidden by a parity selection rule which states that the wavefunctions of the initial and final states of an atomic (ionic) transition must have different parities for it to be permitted. Parity is a property of any function (or quantum mechanical state) that describes the function after mirror reflection. Even functions (states) are symmetric (identical after reflection, for example a cosine function), while odd functions (states) are antisymmetric (for example a sine function). The parity selection rule may be partially removed for an ion (or atom) embedded in host material due to the action of the crystal field, which gives rise to “forbidden lines”. The crystal

field is the electric field created by a host material at the position of the ion.

The parity selection rule is slightly removed by the admixture of 5d states with 4f states and by the disturbed RE ion symmetry due to the influence of the host, which increases with the covalency. Higher covalency implies stronger sharing of electrons between the RE ion and the ligands. This effect is known as the nephelauxetic effect. The resulting absorption–emission lines are characteristic of individual RE ions and quite narrow because they are related to forbidden inner shell 4f transitions.

Judd–Ofelt (JO) analysis allows the oscillator strength of an electric dipole (ED) transition between two states of a trivalent rare earth (RE) ion embedded in a particular host lattice to be calculated. The possible states of an RE ion are often referred to as ^{2S+1}L_J, where L = 0, 1, 2, 3, 4, 5, 6 . . . determines the electron’s total angular momentum, and is conventionally represented by the letters S, P, D, F, G, I. The term (2S + 1) is called the spin multiplicity and represents the number of spin configurations, while J is the total angular momentum, which is the vector sum of the overall (total) angular momentum and the overall spin (**J** = **L** + **S**). The value (2J + 1) is called the multiplicity and corresponds to the number of possible combinations of overall angular momentum and overall spin that yield the same J. Thus, the notation ⁴I_{15/2} for the ground state of Er³⁺ corresponds to the term (J, L, S) = (15/2, 6, 3/2), which has a multiplicity of 2J + 1 = 16 and a spin multiplicity of 2S + 1 = 4. If the wavefunctions |ψ_i⟩ and |ψ_f⟩ correspond to the initial (^{2S+1}L_J) and final (^{2S'+1}L'_{J'}) states of an electric dipole transition of an RE ion, the line strength of this transition, according to JO theory, can be calculated using:

$$S_{\text{ed}} = |\langle \psi_f | H_{\text{ed}} | \psi_i \rangle|^2 = \sum_{k=2,4,6} \Omega_k \left| \left\langle f_{\gamma}^N S' L' J' \left| U^{(k)} \right| f_{\gamma}^N S L J \right\rangle \right|^2, \quad (3.60)$$

where H_{ed} is the ED interaction Hamiltonian, Ω_k are coefficients reflecting the influence of the host material, and $U^{(k)}$ are reduced tensor operator components, which are virtually independent of the host material, and their values are calculated using the so-called intermediate coupling approximation (see [3.70]). The theoretical values of S_{ed} calculated from this are compared with the values derived from experimental data using

$$S_{\text{exp}} = \frac{3hcn}{8\pi^3 e^2 \langle \lambda \rangle} \frac{2J+1}{\chi_{\text{ed}}} \int_{\text{band}} \frac{\alpha(\lambda)}{\rho} d\lambda, \quad (3.61)$$

where $\langle\lambda\rangle$ is the mean wavelength of the transition, h is the Planck constant, c is the speed of light, e is the elementary electronic charge, $\alpha(\lambda)$ is the absorption coefficient, ρ is the RE ion concentration, n is the refraction index and the factor $\chi_{\text{ed}} = (n^2 + 2)^2/9$ is the so-called local field correction. The key idea of JO analysis is to minimize the discrepancy between experimental and calculated values of line strength, S_{ed} and S_{exp} , by choosing the coefficients Ω_k , which are used to characterize and compare materials, appropriately. The complete analysis should also include the magnetic dipole transitions [3.71]. The value of Ω_2 is of prime importance because it is the most sensitive to the local structure and material composition and is correlated with the degree of covalence. The values of Ω_k are used to calculate radiative transition probabilities and appropriate radiative lifetimes of excited states, which are very useful for numerous optical applications. More detailed analysis may be found in, for example, [3.71]. Ω_k values for different ions and host materials can be found in *Gschneidner, Jr. and Eyring* [3.72].

3.3.6 Effects of External Fields

Electroabsorption and the Franz–Keldysh Effect

Electroabsorption is the absorption of light in a device where the absorption is induced by an applied (or changing) electric field within the device. Such a device is an electroabsorption modulator. There are three fundamental types of electroabsorption processes. In the Franz–Keldysh process, a strong applied field modifies the photon-assisted probability of an electron tunneling from the valence band to the conduction band, and thus it corresponds to an effective reduction in the “bandgap energy”, inducing the absorption of light with photon energies of slightly less than the bandgap. It was first observed for CdS, in which the absorption edge was observed to shift to lower energies with the applied field; that is, photon absorption shifts to longer wavelengths with the applied field. The effect is normally quite small but is nonetheless observable. In this type of electroabsorption modulation, the wavelength is typically chosen to be slightly smaller than the bandgap wavelength so that absorption is negligible. When a field is applied, the absorption is enhanced by the Franz–Keldysh effect. In free carrier absorption, the concentration of free carriers N in a given band is changed (modulated), for example, by an applied voltage, changing the extent of photon absorption. The absorption coefficient is proportional to N and to

the wavelength λ of the light raised to some power, typically 2–3. In the confined Stark effect, the applied electric field modifies the energy levels in a quantum well. The energy levels are reduced by the field by an amount proportional to the square of the applied field. A multiple quantum well (MQW) pin-type device has MQWs in its intrinsic layer. Without any applied bias, light with photon energy just less than the QW exciton excitation energy will not be significantly absorbed. When a field is applied, the energy levels are lowered and the incident photon energy is then sufficient to excite an electron and hole pair in the QWs. The relative transmission decreases with the reverse bias V_r applied to the pin device. Such MQW pin devices are usually not very useful in the transmission mode because the substrate material often absorbs the light (for example a GaAs/AlGaAs MQW pin would be grown on a GaAs substrate, which would absorb the radiation that excites the QWs). Thus, a reflector would be needed to reflect the light back before it reaches the substrate; such devices have indeed been fabricated.

The Faraday Effect

The Faraday effect, originally observed by Michael Faraday in 1845, is the rotation of the plane of polarization of a light wave as it propagates through a medium subjected to a magnetic field parallel to the direction of propagation of the light. When an optically inactive material such as glass is placed in a strong magnetic field and plane-polarized light is sent along the direction of the magnetic field, the emerging light’s plane of polarization is rotated. The magnetic field can be applied, for example, by inserting the material into the core of a magnetic coil – a solenoid. The specific rotatory power induced, given by θ/L , has been found to be proportional to the magnitude of the applied magnetic field B , which gives the amount of rotation as:

$$\theta = \vartheta BL, \quad (3.62)$$

where L is the length of the medium, and ϑ is the so-called Verdet constant, which depends on the material and the wavelength of the light. The Faraday effect is typically small. For example, a magnetic field of ≈ 0.1 T causes a rotation of about 1° through a glass rod of length 20 mm. It appears that “optical activity” is induced by the application of a strong magnetic field to an otherwise optically inactive material. There is, however, an important distinction between natural optical activity and the Faraday effect. The sense of rotation θ observed in the

Table 3.9 Verdet constants for some materials

Material	Quartz 589.3nm	Flint glass 632nm	Tb–Ga garnet 632nm	Tb–Ga garnet 1064nm	ZnS 589.3nm	Crown glass 589.3	NaCl 589.3
ϑ (rad m ⁻¹ T ⁻¹)	4.0	4.0	134	40	82	6.4	9.6

Faraday effect for a given material (Verdet constant) depends only on the direction of the magnetic field \mathbf{B} . If ϑ is positive, for light propagating parallel to \mathbf{B} , the optical field \mathbf{E} rotates in the same sense as an advancing right-handed screw pointing in the direction of \mathbf{B} . The direction of light propagation does not change the absolute sense of rotation of θ . If we reflect the wave to pass through the medium again, the rotation increases to

2θ . The Verdet constant depends not only on the wavelength λ but also on the charge-to-mass ratio of the electron and the refractive index $n(\lambda)$ of the medium through:

$$\vartheta = -\frac{(e/m_e)}{2c} \lambda \frac{dn}{d\lambda}. \quad (3.63)$$

Verdet constants for some glasses are listed in Table 3.9.

3.4 Thin Film Optics

Thin film optics involves multiple reflections of light entering a thin film dielectric (typically on a substrate) so that the reflection and transmission coefficients are determined by multiple wave interference phenomena, as shown in Fig. 3.15.

Consider a thin film coated on a substrate. Assuming that the incident wave has an amplitude of A_0 , then there are various transmitted and reflected waves, as shown in Fig. 3.15. We then have the following amplitudes based on the definitions of the reflection and transmission coefficients:

$$\begin{aligned}
 A_1 &= A_0 r_{12} \\
 A_2 &= A_0 t_{12} r_{23} t_{21} \\
 A_3 &= A_0 t_{12} r_{23} r_{21} r_{23} t_{21} \\
 B_1 &= A_0 t_{12} \\
 B_2 &= A_0 t_{12} r_{23} \\
 B_3 &= A_0 t_{12} r_{23} r_{21} \\
 B_4 &= A_0 t_{12} r_{23} r_{21} r_{23} \\
 B_5 &= A_0 t_{12} r_{23} r_{21} r_{23} r_{21} \\
 B_6 &= A_0 t_{12} r_{23} r_{21} r_{23} r_{21} r_{23} \\
 C_1 &= A_0 t_{12} t_{23} \\
 C_2 &= A_0 t_{12} r_{23} r_{21} t_{23} \\
 C_3 &= A_0 t_{12} r_{23} r_{21} r_{23} r_{21} t_{23}
 \end{aligned} \quad (3.64)$$

and so on, where r_{12} is the reflection coefficient of a wave in medium 1 incident on medium 2, and t_{12} is the transmission coefficient from medium 1 into 2. For simplicity, we will assume normal incidence. The phase change upon traversing the thin film thickness d is $\phi = (2\pi/\lambda)n_2d$, where λ is the free space wavelength.

The wave must be multiplied by $\exp(i\phi)$ to account for this phase difference.

The reflection and transmission coefficients are given by

$$\begin{aligned}
 r_1 &= r_{12} = \frac{n_1 - n_2}{n_1 + n_2} = -r_{21}, \\
 r_2 &= r_{23} = \frac{n_2 - n_3}{n_2 + n_3},
 \end{aligned} \quad (3.65a)$$

and

$$\begin{aligned}
 t_1 &= t_{12} = \frac{2n_1}{n_1 + n_2}, \quad t_2 = t_{21} = \frac{2n_2}{n_1 + n_2}, \\
 t_3 &= t_{23} = \frac{2n_3}{n_2 + n_3},
 \end{aligned} \quad (3.65b)$$

where

$$1 - t_1 t_2 = r_1^2. \quad (3.66)$$

Fig. 3.15 Thin film coated on a substrate and multiple reflections of incident light, where n_1, n_2 and n_3 are the refractive indices of the medium above the thin film, the thin film, and the substrate, respectively

The total reflection coefficient is then obtained as:

$$r = \frac{A_{\text{reflected}}}{A_0} = r_1 - \frac{t_1 t_2}{r_1} \sum_{k=1}^{\infty} \left(-r_1 r_2 e^{-i2\phi} \right)^k, \quad (3.67)$$

which can be summed to be:

$$r = \frac{r_1 + r_2 e^{-i2\phi}}{1 + r_1 r_2 e^{-i2\phi}}. \quad (3.68)$$

The total transmission coefficient is obtained as:

$$\begin{aligned} t = \frac{C_{\text{transmitted}}}{A_0} &= -\frac{t_1 t_{23} e^{i\phi}}{r_1 r_2} \sum_{k=1}^{\infty} \left(-r_1 r_2 e^{-i2\phi} \right)^k \\ &= \left(\frac{t_1 t_3 e^{i\phi}}{r_1 r_2} \right) \frac{r_1 r_2 e^{-i2\phi}}{1 + r_1 r_2 e^{-i2\phi}}, \end{aligned} \quad (3.69)$$

which can be summed to be:

$$t = \frac{t_1 t_3 e^{-i\phi}}{1 + r_1 r_2 e^{-i2\phi}}. \quad (3.70)$$

Equations (3.68) and (3.70) are very useful when studying the optical properties of thin films coated on a substrate as discussed by *Gould* in this handbook. (The reader is referred to the chapter on Thin Films by Gould.) In practice, the two most popular approaches are either to analyze optical transmission spectra, which may be observed using a standard spectrophotometer, or ellipsometric investigations of reflection. Both approaches are briefly explained below.

3.4.1 Swanepoel's Analysis of Optical Transmission Spectra

One of the simplest and most practically realizable approaches to the problem was developed by *Swanepoel* [3.73]. He showed that for a uniform film with a thickness d , a refractive index n and an absorption coefficient α deposited on the substrate with a refractive index s , the transmittance can be expressed as

$$T(\lambda) = \frac{Ax}{B - Cx \cos \varphi + Dx^2}, \quad (3.71a)$$

where

$$A = 16n^2 s, \quad (3.71b)$$

$$B = (n+1)^3 (n+s^2), \quad (3.71c)$$

$$C = 2(n^2 - 1)(n^2 - s^2), \quad (3.71d)$$

$$D = (n-1)^3 (n-s^2), \quad (3.71e)$$

$$\varphi = 4\pi n d / \lambda, \quad (3.71f)$$

$$x = \exp(-\alpha d), \quad (3.71g)$$

and n is a function of λ .

For a nonuniform film with a wedge-like cross-section, (3.71a) must be integrated over the thickness of the film, giving

$$T_{\Delta d}(\lambda) = \frac{1}{\varphi_2 - \varphi_1} \int_{\varphi_1}^{\varphi_2} \frac{Ax}{B - Cx \cos \varphi + Dx^2} d\varphi, \quad (3.72)$$

where

$$\varphi_1 = 4\pi n(d - \Delta d) / \lambda$$

and

$$\varphi_2 = 4\pi n(d + \Delta d) / \lambda, \quad (3.73)$$

where d is the average thickness of the film and Δd is the variation of the thickness throughout the illumination (testing) area. The concept behind Swanepoel's method is to construct two envelopes $T_M(\lambda)$ and $T_m(\lambda)$ that pass through the maxima and minima of $T(\lambda)$ and to split the entire spectral range into three regions: negligible absorption, weak absorption and strong absorption regions, as shown in Fig. 3.16.

Fig. 3.16 Optical transmission of a-Se thin film. Calculations are done using (3.71) with the $n(\lambda)$ and $\alpha(\lambda)$ relations shown in Fig. 3.17. The film was prepared by the thermal evaporation of photoreceptor-grade selenium pellets. Film thickness was $2 \mu\text{m}$. Tentative regions of strong, weak and negligible absorption are also shown

Fig. 3.17 (a) The spectral dependence of the refractive index of the a-Se thin film from Fig. 3.16. The line corresponds to the Cauchy approximation with the parameters shown on the figure. (b) The spectral dependence of the absorption coefficient of the same a-Se thin film

In the region of negligible absorption, (3.72) yields

$$T_{M/m} = \frac{\lambda}{2\pi n \Delta d} \frac{a}{\sqrt{1-b^2}} \tan^{-1} \left[\frac{1 \pm b}{\sqrt{1-b^2}} \tan \left(\frac{2\pi n \Delta d}{\lambda} \right) \right], \quad (3.74)$$

where $a = A/(B+D)$ and $b = C/(B+D)$. The “plus” sign in (3.74) corresponds to transmission maxima and “minus” to minima. Equation (3.74) is used to find Δd and n .

In the region of weak absorption,

$$T_{M/m} = \frac{\lambda}{2\pi n \Delta d} \frac{a_x}{\sqrt{1-b_x^2}} \tan^{-1} \left[\frac{1 \pm b_x}{\sqrt{1-b_x^2}} \tan \left(\frac{2\pi n \Delta d}{\lambda} \right) \right], \quad (3.75)$$

where $a_x = Ax/(B+Dx^2)$ and $b_x = Cx/(B+Dx^2)$. Equation (3.75) allows us to find x and n using the previously found Δd .

The previous results are used to construct $n(\lambda)$ and to create approximations using the Cauchy, Sellmeier or

Wemple–Di Dominico dispersion equations. An example of a Cauchy approximation is shown in Fig. 3.17.

The positions of the extrema are given by the equation

$$2nd = m\lambda, \quad (3.76)$$

where $m = 1, 2, 3, \dots$ for maxima and $m = 1/2, 3/2, \dots$ for minima. Therefore, d can be found from the slope of (n/λ) versus m .

In the region of strong absorption, the absorption coefficient is calculated as

$$x = \frac{A - \sqrt{A^2 - 4T_i^2 BD}}{2T_i D}, \quad (3.77)$$

where

$$T_i = \frac{2T_M T_m}{T_M + T_m} \quad (3.78)$$

and A , B and D are calculated using the above-mentioned $n(\lambda)$ approximation.

It is worth noting that the division into negligible absorption, weak absorption and strong absorption regions is quite arbitrary and should be checked using trial-and-error methods.

3.4.2 Ellipsometry

Ellipsometry measures changes in the polarization of light incident on a sample in order to sensitively characterize surfaces and thin films, for example. Interactions of the polarized light with the sample cause a change in the polarization of the light, which may then be measured by analyzing the light reflected from the sample. The plane-polarized light incident on the sample can be resolved into two components – the component parallel to the plane of incidence (the p-component), and the component perpendicular to it (the s-component). That is, the incident light can be resolved into two components E_p (incident) and E_s (incident), where E refers to the electric field in the light wave, and similarly, the reflected light can be resolved into two components E_p (reflected) and E_s (reflected), enabling so-called Fresnel reflection coefficients, $R_p = E_p$ (reflected)/ E_p (incident) and $R_s = E_s$ (reflected)/ E_s (incident), to be obtained for the p- and s-components, respectively. Ellipsometry measures ρ , the ratio of these two coefficients, which is given by:

$$\rho = (R_p/R_s) = e^{i\Delta} \tan(\Psi), \quad (3.79)$$

where ρ is expressed in terms of the so-called ellipsometric angles Ψ ($0^\circ \leq \Psi \leq 90^\circ$) and Δ ($0^\circ \leq \Delta \leq 360^\circ$). These angles are defined as $\Psi = \tan^{-1} |\rho|$ and the differential phase change, $\Delta = \Delta_p - \Delta_s$. Thus, ellipsometry measures a change in the polarization, expressed as Ψ and Δ , in order to characterize materials. Because ellipsometry measures the ratio of two values, it can be made to be highly accurate and reproducible. The ratio ρ is a complex number; it contains the “phase” information Δ , which makes the measurement very sensitive. However, establishing values for Ψ and Δ is not particularly useful in itself for sample characterization. What one really wants to determine are the parameters of the sample, including, for example, the film thickness, optical constants, and the refractive index. These characteristics can be found by using the measured values of Ψ and Δ in an appropriate model describing the interaction of light with the sample. As an example, consider light reflected off an optically absorbing sample in air (in other words, with a refractive index of unity). The sample can be characterized by a complex refractive index $n - ik$, where n and k are the sample’s refractive index and extinction coefficients at a particular wavelength. From Fresnel’s equations, assuming that the light is incident at an angle ϕ to the sample normal, one gets

$$\begin{aligned} n^2 - k^2 &= \sin^2(\phi) [1 + \{\tan^2(\phi) \\ &\times [\cos^2(2\Psi) - \sin^2(2\Psi) \sin^2(\Delta)] \\ &/ [1 + \sin(2\Psi) \cos(\Delta)]^2\}] \end{aligned} \quad (3.80a)$$

and

$$\begin{aligned} 2nk &= \sin^2(\phi) \tan^2(\phi) \sin(4\Psi) \sin(\Delta) \\ &/ [1 + \sin(2\Psi) \cos(\Delta)]^2. \end{aligned} \quad (3.80b)$$

Since the angle ϕ is set in the experiment, the two parameters measured from the experiment (Ψ and Δ) can be used to deduce the two remaining unknown variables in the equation above – namely, n and k . For a given model (a given set of equations used to describe the sample), the mean squared error between the model and the measured Ψ and Δ values is minimized, typically using the Marquardt–Levenberg algorithm, in order to quickly determine the minimum or best fit within some predetermined confidence limits. Thus, the n and k values are established using this procedure. In practice, ellipsometers consist of a source of linearly polarized light, polarization optics, and a detector. There are a number

of different approaches to conducting an ellipsometry experiment, including null ellipsometers, rotating analyzer/compensator ellipsometers, and spectroscopic ellipsometers. Each of these approaches is discussed briefly below.

Historically, the first ellipsometers that were developed were null ellipsometers. In this configuration, the orientation of the polarizer, compensator and analyzer are adjusted such that the light incident on the detector is extinguished or “nulled”. It should be noted that there are 32 combinations of polarizer, compensator and analyzer angles that can result in a given pair of Ψ and Δ values. However, because any two angles of the polarizer, compensator and analyzer that are 180° apart are optically equivalent, only 16 combinations of angles need to be considered if all angles are restricted to values below 180° . However, even when automated, this approach is thus inherently slow and spectroscopic measurements are difficult to make. However, this configuration can be very accurate and has low systematic errors. In order to speed up measurements, rotating analyzer/polarizer ellipsometers were developed. In these systems, either the analyzer or polarizer is continuously rotated at a constant angular velocity (typically about 100 Hz) about the optical axis. The operating characteristics of both of these configurations are similar. However, the rotating polarizer system requires the light source to be totally unpolarized. Any residual polarization in the source results in a source of measurement error unless corrected. Similarly, a rotating analyzer system is susceptible to the polarization sensitivity of the detector. However, solid state semiconductor photodetectors have extremely high polarization sensitivities. Thus, commercial systems tend to use rotating analyzer systems where residual polarization in the source is not an issue. In this case, the (sinusoidal) variation in the amplitude of the detector signal can be directly related to the ellipticity of the reflected light – Fourier analysis of this output provides values for Ψ and Δ . Such systems can provide high-speed, accurate measurements and the lack of a compensator actually improves the measurement by eliminating any errors associated with these components. Spectroscopic ellipsometers extend the concepts developed for measurement at a single wavelength to measurements at multiple wavelengths – typically as many as 40 wavelengths. Being able to measure the dispersion in optical constants with wavelength adds another dimension to the analysis, permitting unambiguous determinations of material and structure parameters.

3.5 Optical Materials

3.5.1 Abbe Number or Constringence

In an optical medium, the Abbe number is defined as the inverse of its dispersive power; that is, it represents the relative importance of refraction and dispersion. There are two common definitions based on the use of different standard wavelengths. The Abbe number ν_d is defined by:

$$\nu_d = (n_d - 1)/(n_F - n_C), \tag{3.81}$$

where n_F , n_d and n_C are the refractive indices of the medium at the Fraunhofer standard wavelengths corresponding to the helium d-line ($\lambda_d = 587.6$ nm, yellow), the hydrogen F-line ($\lambda_F = 486.1$ nm, blue) and the hy-

drogen C-line ($\lambda_C = 656.3$ nm, red), respectively. The Abbe number of a few glasses are listed in Table 3.10. The Abbe number ν_e , on the other hand, is defined by

$$\nu_e = (n_e - 1)/(n_{F'} - n_{C'}) : \tag{3.82}$$

where n_e , $n_{F'}$ and $n_{C'}$ are the refractive indices at wavelengths of the e-line (546.07 nm), the F'-line (479.99 nm) and the C'-line (643.85 nm), respectively.

The relationship between the refractive index n_d and the Abbe number ν_d is given by the Abbe diagram, where n_d is plotted on the y-axis against its corresponding ν_d value for different glasses, usually with the Abbe numbers decreasing on the x-axis, as shown in Fig. 3.18.

3.5.2 Optical Materials

Optical materials are those crystalline solids and glasses that are commonly used in the construction of optical components, such as lenses, prisms, window, mirrors and polarizers. In addition to having the required optical properties, such as a well defined refractive index n with a known dependence on wavelength $n = n(\lambda)$ and temperature, optical materials should also have various other desirable material properties, such as good homogeneity (including negligible macroscopic variations in the refractive index), negligible thermal expansion (small α_L , thermal expansion coefficient), resistance to mechanical damage (resistance to scratching), and resistance to chemical degradation (chemical corrosion, staining). Also, in the case of optical glasses, it is desirable to have negligible air (or gas) bubbles incorporated into the glass structure during fabrication (during shaping for example), negligible stress-induced birefringence, negligible nonlinear properties (unless used specifically due to its nonlinearity), and negligible fluorescence. In all of these cases, negligible implies less than a tolerable quantity within the context of the particular optical application. For example, at a given wavelength and for many glass materials used in optics, n should not vary by more than 10^{-5} , while 10^{-6} is required for certain optics applications in astronomy. In addition, they should have good or reliable man-

Fig. 3.18 The Abbe diagram is a diagram in which the refractive indices n_d of glasses are plotted against their Abbe numbers in a linear n_d versus ν_d plot and, usually, with the Abbe number decreasing along the x-axis, rather than increasing. A last letter of F or K represents flint or crown glass. Other symbols are as follows: S, dense, L, light; LL, extra light; B, borosilicate; P, phosphate; LA or La, lanthanum; BA or Ba, barium. Examples: BK, dense flint; LF, light flint; LLF, extra light flint; SSK, extra dense crown; PK, phosphate crown; BAK, barium crown; LAF, lanthanum flint

Table 3.10 Abbe numbers for a few glasses. PC denotes polycarbonate, PMMA is polymethylmethacrylate, and PS represents polystyrene

Optical glass →	SF11	F2	BaK1	Crown glass	Fused silica	PC	PMMA	PS
ν_d →	25.76	36.37	57.55	58.55	67.80	34	57	31

Table 3.11 The refractive indices, n_d , and Abbe numbers, v_d , (3.81) of selected optical materials (compiled from the websites of Oriel, Newport and Melles-Griot); n_d at $\lambda_d = 587.6$ nm, α_L is the linear thermal expansion coefficient

Glasses	Transmission (typical, nm)	n_d	v_d	Applications	Comment
Fused silica	175–2000	1.45846	67.8	Lenses, windows, prisms, interferometric FT-IR components. UV lithography	Synthetic. Has UV properties; transmittance and excellent thermal low α_L . Resistant to scratching
SF 11, flint	380–2350	1.78472	25.76	Lenses, prisms	Flint glasses have $v_d < 50$
LaSFN9, flint	420–2300	1.85025	32.17	Lenses, prisms	High refractive index. More lens power for less curvature
BK7, borosilicate crown	380–2100	1.51680	64.17	Visible and near IR optics. Lenses, windows, prisms, interferometric components	All around excellent optical lens material. Not recommended for temperature-sensitive applications
BaK1, barium crown	380–2100	1.57250	57.55	Visible and near IR optics. Lenses, windows, prisms, interferometric components	All around excellent optical lens material. Not recommended for temperature-sensitive applications
Optical crown	380–2100	1.52288	58.5	Lenses, windows, prisms, interferometric components	Lower quality than BK7
Pyrex, borosilicate glass		1.43385	66	Mirrors	Low thermal expansion
Crystals					
CaF ₂ crystal	170–7000	1.43385	94.96	Lenses, windows for UV optics, especially for excimer laser optics	Sensitive to thermal shock
MgF ₂ crystal	150–7000	$n_0 = 1.37774$ $n_e = 1.38956$		Lenses, windows, polarizers, UV transmittance	Positive birefringent crystal. Resistant to thermal and mechanical shock
Quartz, SiO ₂ crystal	150–2500	$n_0 = 1.54431$ $n_e = 1.55343$		UV optics. Wave plates. Polarizers	Positive uniaxial birefringent crystal
Sapphire, Al ₂ O ₃ crystal	150–6000	1.7708 (546.1 nm)		UV-Far IR windows, high power laser optics	High surface hardness, Scratch resistant. Chemically inert
Auxiliary optical materials					
ULE SiO ₂ -TiO ₂ glass				Optical spacers	Very small thermal expansion
Zerodur, glass ceramic composite		1.5424	56–66	Mirror substrates. Not suitable for transmission optics due to internal scattering	Ultra-low α_L . Fine mixture of glass and ceramic crystals (very small size)

ufacturability at an affordable cost. There are various useful optical materials which encompass not only single crystals (such as CaF_2 , MgF_2 , quartz, sapphire) but also a vast range of glasses (which are supercooled liquids with high viscosity, such as flint and crown glasses as well as fused silica). Higher refractive index materials have more refractive power and allow lens designs that need less curvature to focus light, and hence tend to give fewer aberrations. Flint glasses have a larger refractive index than crown glasses. On the other hand, crown glasses are chemically more stable, and can be produced more to specification. While most optical materials are used for their optical properties (such as in optical transmission), certain “optical” materials (auxiliary materials) are used in optical applications such as mirror substrates and optical spacers for their nonoptical properties, such as their negligible thermal expansion coefficients. Some optical properties of selected optical materials and their applications are listed in Table 3.11.

3.5.3 Optical Glasses

Optical glasses are a range of noncrystalline transparent solids used to fabricate various optical components, such as lenses, prisms, light pipes and windows. Most (but not all) optical glasses are either crown (K) types or flint (F) types. K-glasses are usually soda-lime-silica glasses, whereas flint glasses contain substantial lead oxide; hence F-glasses are denser and have higher refractive powers and dispersions. Barium glasses contain barium oxide instead of lead oxide and, like lead glasses, have high refractive indices, but lower dispersions. There are

other high refractive index glasses, such as lanthanum- and rare earth-containing glasses. Optical glasses can also be made from various other glass formers, such as boron oxide, phosphorus oxide and germanium oxide. The Schott glass code or number is a special number designation (511 604.253 for Schott glass K7) in which the first three numbers (511) represent the three decimal places in the refractive index ($n_d = 1.511$), the next three numbers (604) represent the Abbe number ($v_d = 60.4$), and the three numbers after the decimal (253) represent the density ($\rho = 2.53 \text{ g/cm}^3$). A different numbering system is also used, where a colon is used to separate n_d and v_d ; for example, 517:645 for a particular borosilicate crown means $n_d = 1.517$, $v_d = 64.5$ (see also Sect. 3.5.1).

In the Schott glass coding system, optical glasses are represented by letters in which a last letter of K refers to crown, and F to flint. The first letters usually represent the most important component in the glass, such as P in the case of phosphate. The letters Kz (“Kurtz”), L (“leicht”) and S (“schwer”) before K or F represent short, light and dense (heavy) respectively (from German). S after K or F means “special”. Examples include: BK, borosilicate crown; FK, fluor crown; PK, phosphate crown; PSK, dense phosphate crown; BaLK, light barium crown; BaK, barium crown; BaSK, dense barium crown; SSK, extra dense barium crown; ZnK, zinc crown; LaK, lanthanum crown; LaSK, dense lanthanum crown; KF, crown flint; SF, dense flint; SFS, special dense flint; BaF, barium flint; BaLF, barium light flint; BaSF, dense barium flint; LLF, extra light flint; LaF, lanthanum flint.

4. Magnetic Properties of Electronic Materials

This work reviews basic concepts from both traditional macroscopic magnetism and unconventional magnetism, in order to understand current and future developments of submicronic spin-based electronics, where the interplay of electronic and magnetic properties is crucial. Traditional magnetism is based on macroscopic observation and physical quantities are deduced from classical electromagnetism. Physical interpretations are usually made with reference to atomic magnetism, where localized magnetic moments and atomic physics prevail, despite the fact that standard ferromagnetic materials such as Fe, Co and Ni are not localized-type magnets (they have extended s and localised d electronic states). While this picture might be enough to understand some aspects of traditional storage and electromechanics, it is not sufficient when describing condensed matter systems with smaller length scales (progressing toward the nanometer range). In this case, the precise nature of the magnetism (localized, free or itinerant as in Fe, Co and Ni transition metals) should be accounted for, along with the simultaneous presence of charge and spin on carriers. In addition, when we deal with the thin films or multilayers found in conventional electronics, or with objects of reduced dimensionality (such as wires, pillars, dots or grains), the magnetic properties are expected to be different from conventional three-dimensional bulk systems.

This chapter is organized as follows. We begin (in the Introduction) by highlighting the new era of submicronic spin-based electronics, and we

4.1	Traditional Magnetism	81
4.1.1	Fundamental Magnetic Quantities	81
4.1.2	The Hysteresis Loop	83
4.1.3	Intrinsic Magnetic Properties	87
4.1.4	Traditional Types of Magnetism and Classes of Magnetic Materials	90
4.2	Unconventional Magnetism	93
4.2.1	Conventional and Unconventional Types of Exchange and Coupling in Magnetic Materials	93
4.2.2	Engineering and Growth of Thin Magnetic Films	94

present a table of papers on the topics we cover in the chapter, for the reader who wishes to learn more. The traditional elements of magnetism, such as the hysteresis loop, conventional types of magnetism and magnetic materials, are then presented (in Sect. 4.1). We then briefly describe (in Sect. 4.2) unconventional magnetism, which can be used to understand new high-tech materials that will be used in future devices based on spintronics and quantum information.

Digital information technology involves three main activities:

- Processing of information (using transistors, logic gates, CPU, RAM, DSP...)
- Communication of information (using networks, switches, cables, fibers, antennae...)

- Storage of information (using tapes, hard disks, CD, DVD, flash memory...)

The application of magnetism to such technologies has traditionally been confined to information storage, originating from the development of bubble and ferrite core technologies, when RAM memory was based on

magnetism. RAM memory is a special type of nonpermanent (primary) information storage device, which can be distinguished from permanent (secondary) or mass information storage devices such as tapes, hard disks, floppy and zip disks, CDs, *DVDs*, and flash memory.

The field of applied magnetism is currently undergoing much transformation due to several recent developments, among which is the progress toward the nanometer scale in integrated circuits. At this length scale, quantum effects become extremely important and carrier spin becomes of interest since it may be conserved over this length scale and so could be used to carry and manipulate information. This would pave the way towards the fabrication of new devices based on charge and spin (spintronic devices) instead of just charge, as used in traditional microelectronics. This means that new types of junctions and transistors could be built that would use magnetism to tackle the processing of information.

Quantum effects have already been used in many products, since they are the basis of the *GMR* effect (Table 4.1) that is the basis for the recent surge towards

extremely high densities in hard disks; however, the longer-term intention is to make use of these effects in basic components of *quantum computers* and *quantum communication devices*. The quantum computer is based on the *qubit* (quantum bit), which is the basic unit of information used in a quantum computer (equivalent to the classical bit used in conventional computing). If we consider a sphere, the classical bit can be viewed as an object with two possible states at the north and the south poles of the sphere, whereas a qubit is an object that can sit anywhere on the surface of the sphere (called the *Bloch sphere*; see *Nielsen and Chuang* [4.25]). A quantum computer can perform a massive number of computations in parallel, since one is allowed to access any superposition of states at any time in quantum mechanics due to its linearity, in contrast to a classical von Neumann type of computer, where one only has access to a single state at any time (Table 4.1). Quantum communications are extremely secure, since a caller may build a coherent state with the callee where any intrusion can perturb the coherence, providing very efficient detection.

From a fundamental point of view, one can start by representing a magnetic material by a single magnetic moment and then studying its behavior, before investigating the many interacting moments that are the building blocks of magnetic materials. From an applied point of view, the orientation of the moment defines the value

of the bit. Once the orientation of the moment has been linked to a bit value, it becomes important to understand the physical processes, the energetics and the dynamics of the change in moment orientation (moment reversal from left to right or moment flip from up to down) in order to be able to control, alter and predict the bit value.

4.1 Traditional Magnetism

Classical magnetism relates to magnetic moments and their behavior when an external field, mechanical stress or some other perturbing effect is applied. The idea is to investigate the way that the energy of the magnetic moment changes with time. In order to describe the different magnetic energy terms that control the behavior of a moment, we can start from a single isolated moment in vacuum, at zero temperature ($T = 0$ K), zero applied magnetic field ($\mathbf{H} = 0$) and zero frequency ($f = 0$). It is obvious that the energy is zero from a classical point of view (quantum mechanically, however, it is worth noting that, even at $T = 0$ K, quantum fluctuations exist that could disorient, flip or reverse the moment).

The next step is to apply a magnetic field \mathbf{H} ($T = 0$ K, $f = 0$); we then obtain the Zeeman energy $E_Z = -\mathbf{M} \cdot \mathbf{H}$, with \mathbf{M} representing the moment. If we place the moment in an unbounded (of infinite size) crystal, it is clear that the energy of the moment is anisotropic, since the direction of the moment (called an easy axis direction) is imposed by the internal symmetry of the crystal, in contrast to the case in vacuum, where \mathbf{M} is free to point in any direction. The crystal may possess a set of easy axes (easy planes), in which case the moment will point in one of several directions (or any direction in one of several planes).

If the body containing the moment has a finite size, a new energy must be accounted for: the demagnetization energy. Magnetic surface charges (poles) induced on the surface bounding the body create a demagnetizing field inside the body (this is called the stray field outside of the body). The demagnetization energy is also called the shape anisotropy energy or the magnetostatic energy because it is (approximately) expressed (for ellipsoidal bodies) as $2\pi N_{\alpha\beta} \mathbf{M}_\alpha \mathbf{M}_\beta$, where $N_{\alpha\beta}$ is a set of factors (demagnetization coefficients) that depend on the shape of the body (the Einstein summation convention is used for repeated indices).

Now suppose we include several local moments in a material. If sites i and j carrying moments \mathbf{M}_i and \mathbf{M}_j

are close enough, we then have an interaction energy between them called the exchange energy $-A_{ij} \mathbf{M}_i \mathbf{M}_j$, which will align moments \mathbf{M}_i and \mathbf{M}_j if A_{ij} is positive (ferromagnetic interaction). If A_{ij} is negative, the moments will align antiparallel to each other (antiferromagnetic interaction). In a ferromagnet we have a net moment, whereas in an antiferromagnet the net moment is zero.

The above description considers localized magnetism in distinct atoms (such as in a gas), ions, molecules or in special materials (like insulators or rare-earth solid state compounds possessing external-shell f electrons with highly atomic-like character). If we have a conducting material with free electrons interacting with localized atoms/ions/molecules (for transition metals with s and d electrons or magnetic semiconductors for example), a different type of magnetism called itinerant magnetism occurs. Nevertheless, it is possible to extend the notion of the magnetic moment to this case, accounting for the combined effects of free and localized charges modeled as an effective number of Bohr magnetons (see Sect. 4.2.1, Table 4.1 and Table 4.2).

The different physical mechanisms and types of magnetism briefly described above operate at different length scales. In order to gain some perspective and be able to ponder what lies ahead in terms of possible developments and hurdles, Fig. 4.1 gives a summary of different mechanisms, characterization methods and manufacturing processes along with their corresponding length scales. Note that, on the nanometer scale, the device size becomes comparable to most ranges of interactions encountered in magnetic materials, and this will trigger the development of novel effects and devices.

4.1.1 Fundamental Magnetic Quantities

Magnetization is the fundamental property exhibited by a magnetic substance. It originates from its electrons, as with the electric dipole moment. It can be

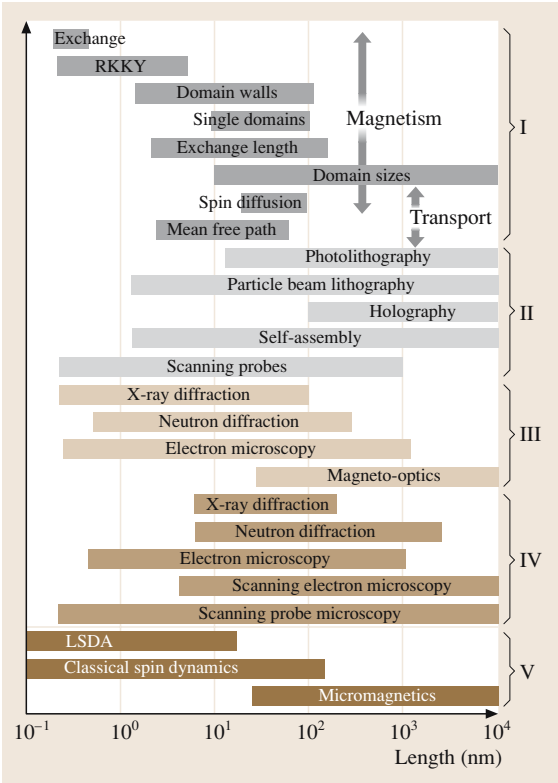

Fig. 4.1 Typical lengths of interest in magnetic materials and spintronics (in relation to basic phenomena, interactions and transport). Diagnostic techniques in III are depth profiling techniques and IV is for surface probing techniques) of interest in magnetic materials are also shown along with their probing lengths. II indicates growth methods and V theoretical characterization techniques. **LSDA** (local spin density approximation) is the spin counterpart of the density function theory (**DFT**) used to calculate band structure. Since most interaction lengths (shown in I) range between 1 and 100 nm, device size is comparable to interaction range in nanoelectronics (after [4.28])

intrinsic (it can exist without the application of any external field) or it can be induced by an external magnetic field. In atoms/molecules/ions and rare-earth solids, magnetization is created from individual atom-like localized magnetic moments. In the solid state, the moment is generally defined by the band structure and an effective moment can be defined in terms of a *Bohr magneton* $\mu_B = e\hbar/2m$, the magnetic moment carried by a single electron (e and m are the electron charge and mass). Magnetization is a thermodynamic quantity that changes with temperature, mechanical

Table 4.2 Selected ferromagnetic solids with their saturation magnetizations M_s , effective Bohr magnetons n_B and Curie temperatures [4.27]

Substance	M_s (G) at 300 K	M_s (G) at 0 K	n_B at 0 K	Curie T_c (K)
Fe	1707	1740	2.22	1043
Co	1400	1446	1.72	1388
Ni	485	510	0.62	627
Gd	–	2060	7.63	292
Dy	–	2920	10.2	88
MnAs	670	870	3.4	318
MnBi	620	680	3.52	630
CrO ₂	515	–	2.03	386
EuO	–	1920	6.8	69

stress and chemical processes such as alloying (see *Chikazumi* [4.26]).

When a field is applied to a magnetic substance, the largest acquired magnetization M_s measured along the direction of the applied field is the saturation magnetization, meaning that all moments are aligned parallel to the field. Since increasing the temperature T causes more moments to misalign, one can define the saturation at $T = 0$ K with $M_s = Nn_B\mu_B$, where N is the number of ions, atoms or molecules, and n_B the effective number of Bohr magnetons (see Table 4.2).

The number n_B is different for atoms/ions/molecules and solids and is determined by the electronic state; for example, for Fe^{3+} ions it is 5 (according to Hund rules, see *Jansen* [4.11]), since we have a $3d^5$ configuration (the orbital contribution is neglected), whereas for Fe atoms it is 2 ($3d^8$ configuration). Trivalent rare-earth ions with highly localized 4f orbitals possess magnetic moments that are determined by $g_J[J(J+1)]^{1/2}$, where g_J is the Landé factor and J the total angular momentum. Transition metal ions possess magnetic moments that are determined by $2[S(S+1)]^{1/2}$, where S is the total spin of the ion (there is no orbital contribution because of orbital moment quenching, see *Kittel* [4.27]). In the solid state, for example for ferromagnetic metals, n_B is determined from the band structure (Table 4.1). At lower dimensions (clusters, dots, thin films...), n_B tends to increase because of lower symmetry and coordination (high symmetry and coordination tend to decrease it). Among the elements, the rare-earth ions (Dy^{3+} , Ho^{3+} and Er^{3+}) possess large values of n_B – on the order of 10 – whereas solids such as Gd-based garnets (see *Wigen* [4.16]) have n_B values on the order of 15 (at $T = 0$ K).

The moment due to angular momentum is given in the localized case (atoms/ions/molecules) by: $-g_L\mu_B\mathbf{L}$ (for orbital angular momentum \mathbf{L}), where $g_L = 1$ (the orbital Landé factor), or by $-g_S\mu_B\mathbf{S}$ (for spin angular momentum \mathbf{S}), where $g_S = 2$ (the spin Landé factor). In the case of an atom/ion with a total angular momentum $\mathbf{J} = \mathbf{L} + \mathbf{S}$, the moment is given by $-g_J\mu_B\mathbf{J}$, where:

$$g_J = 1 + [J(J+1) + S(S+1) - L(L+1)]/2J(J+1)$$

which is the total Landé factor. In the solid state, the Landé factor is determined from the band structure (using the spin-splitting of electron or hole bands in the presence of a magnetic field). It may become negative, anisotropic (a tensor) and depend on the wavevector \mathbf{k} . Typical values of g for semiconductors at $\mathbf{k} = 0$ include: InSb, $g = -44$; GaAs, $g = 0.32$; InAs, $g = -12$ [4.11, 21].

4.1.2 The Hysteresis Loop

When a magnetic field is applied to a ferromagnetic material [4.27], a change in magnetization takes place. The straightforward way to understand the underlying phenomena is to plot the magnetization \mathbf{M} along the direction of the applied field \mathbf{H} . The locus of the magnetization depicted in the \mathbf{M} - \mathbf{H} plane is the hysteresis loop (Fig. 4.2).

The term hysteresis means that when the material is field-cycled (in other words, when the field \mathbf{H} is increased then decreased), two different nonoverlapping curves $\mathbf{M}(\mathbf{H})$ are obtained. Another approach involves plotting the induction \mathbf{B} versus \mathbf{H} , since it is \mathbf{B} that is ac-

Fig. 4.2 Hysteresis loop showing the fundamental points in the \mathbf{M} - \mathbf{H} plane, such as the saturation magnetization M_s , the remanent M_r , the coercive field H_c (for which $M = 0$) and the saturation field H_{sat} (for which $M = M_s$), as well as the initial magnetization curve (dashed) with initial permeability μ_{ini} (after [4.29])

tually measured. Several points in the \mathbf{M} - \mathbf{H} plane shown in the figure are worth mentioning. Point d is where the magnetization reaches its largest value M_s (the saturation magnetization). Points i and f denote the magnetic fields $\pm H_c$ for which the magnetization is zero. The magnetic field H_c is called the coercive field; it is generally large for hard materials and small for soft magnets. Points e and h denote the remanent magnetization M_r , which is the magnetization that remains after the applied field is switched off, which is the hallmark of permanent magnets.

The ratio M_r/M_s , called the squareness, is close to 1 when the applied magnetic field is closely aligned with the easy axis (and so the hysteresis loop is squarer). Once the easy axis (or set of easy axes) is determined, the angle between the easy axis and the magnetic field (ϕ , say) is varied and the hysteresis loop is plotted for different angles. When the angle ϕ is increased, the opening of the hysteresis loop is reduced; it is largest when the magnetic field is parallel to the easy axis and smallest when the magnetic field is parallel to the so-called hard

Fig. 4.3 Hysteresis loop obtained for an arbitrary angle ϕ between the magnetic field and the anisotropy axis (easy axis). Associated quantities such as coercive field H_c , remanent magnetization M_r and field H_r (given by the intersection of the tangent to the loop at $-H_c$ and the M_r horizontal line) are shown. The tangent to the loop at $-H_c$ is also called the maximum differential permeability. The *thick line* is the hysteresis loop when the field is along the hard axis and H_k (the anisotropy field) is the field value at the slope break where the magnetization reaches its saturation value M_s . Quantities such as H_c , M_r , H_r and μ_{max} depend on the angle ϕ . When the field is along the easy axis, the coercive field reaches its largest value (the hysteresis loop is broadest), at which point the magnetization jumps (at $\pm H_c$)

axis. All of these characteristics of the hysteresis loop are depicted in Fig. 4.3, and for a given temperature and frequency of the applied field H , quantities such as the remanent magnetization M_r , the remanent field H_r , the coercive field H_c and the maximum differential permeability μ_{\max} vary with the angle ϕ ;

In addition, the hysteresis loop changes and may even disappear altogether above a given temperature (Curie temperature), and it can be seriously altered by changing the frequency of the field (see below).

The Magnetization Process Viewpoint

When a magnetic field is applied to a material, a magnetization process takes place. This means that a change in magnetization can occur according to any of the following routes. At low applied magnetic field (and low frequency), domain boundaries bulge (this is a reversible regime, implying that if we decrease the field again, the magnetization will go back to the initial state by following the same path). This is called the domain nucleation and pinning process (see Fig. 4.4). At higher fields the walls are depinned and free to move. This is an irreversible regime (in contrast to the low-field case), meaning that, if we decrease the field, the change in magnetization upon field variation will not follow the same path. This regime is the free domain wall movement regime. At higher fields (or frequencies), the magnetization changes through the rotation of moments. In this case we have two possibilities: if the material is homogeneous and therefore behaves as if there is a single moment in the material, we get the coherent rotation regime (this is well described by the Stoner–Wohlfarth model, see Table 4.1). On the other hand, if the magnetization changes in a material in an inhomogeneous way (different points in the sample undergo

different magnetization changes), we obtain a curling process [4.26]. Finally, if the magnetic field is applied along the easy axis and then suddenly reversed, the magnetization changes with a switching process, meaning the moment jumps from a positive value to a negative value of the same magnitude without any rotation process, since the magnetization is already along the easy axis.

The Energetics Viewpoint

Hysteretic behavior can be viewed as stemming from the motion of the energy minimum as the field is varied. In Fig. 4.5 the field is cycled in a clockwise fashion. The energy minimum is displayed for several values of the field. Hysteresis is shown to arise from the asymmetric behavior of the energy with the magnetization as the field is cycled. The loss of hysteresis is given by the area circumscribed by the hysteresis loop. Since soft materials have thinner hysteresis loops (equivalent to smaller coercivity) than hard materials their losses are smaller.

The Signal Processing Viewpoint

If we apply a time-dependent field $H(t)$ to the magnetic material and monitor the magnetization $M(t)$ as the output, then the relation $M(t) = F[H(t)]$ is that of a nonlinear filter. The magnetic material acts as a nonlinear filter because M is not proportional to H except at very low fields. This nonlinearity is easily observed if $M(t)$ is monitored as a square signal with a sinusoidal input excitation $H(t)$ (Fig. 4.6). In addition, the material imposes a delay in signal propagation that is proportional to the width of the hysteresis loop (twice the coercive field). Hysteretic behavior means that different values of output are obtained when the input excitation is in-

Fig. 4.4 Reversible and irreversible motion of the magnetization M with the field H . For small fields, $H < H_c$ and initial magnetization, Rayleigh's law is valid along a–b, but for large H , saturation is induced in M through irreversible domain boundary motion along b–c followed by rotation of magnetization along c–d. When the field is reversed along d–e–f towards $-H_c$, the variation in magnetization is not exactly the same as seen previously, and this is why a different $M(H)$ curve is obtained. Reversible movement at low field means that domain walls are pinned by impurities and they simply bulge under the action of H (O–a), whereas jerky irreversible movement is associated with depinning of the domain walls (a–b), creating Barkhausen noise. Free irreversible movement beyond the pinning centers is depicted on the right (after [4.29])

creased or decreased, and this phenomenon is widely exploited (in control systems for instance).

The Information Storage Viewpoint

Obtaining a nonzero response (M) at zero excitation ($H=0$) is a phenomenon known as remanence (we call this remanent value M_r). The major advantage of remanence (in addition to its usefulness in permanent magnets) is that information (the value of M_r) can be stored without any excitation source ($H=0$). Since we have M_r when the signal is decreased (we call this M_{r1}), we ought to get a different M_r when the signal is increased (we call this M_{r2}) due to hysteresis. In this case we get two bit values (0 for M_{r1} and 1 for M_{r2}). This contrasts sharply with electronic storage, where a voltage must be maintained in order to maintain the charge (representing the information); see Chapt. 51.

The Electromagnetic Compatibility and Frequency Synthesis Viewpoint

Hysteretic behavior can be viewed as the flux ϕ (corresponding to the magnetization M) induced in a circuit by an exciting current $i(t)$ at time t (corresponding to field H). The resulting relationship $\phi[i(t)]$ is a nonlinear characteristic that can be expanded as:

$$\phi[i(t)] = a_0 + a_1 i(t + \tau) + a_2 [i(t + \tau)]^2 + a_3 [i(t + \tau)]^3 + a_4 [i(t + \tau)]^4 + \dots,$$

where τ accounts for the response delay of the flux (the larger the delay, the broader the hysteresis curve). Ordinary linear inductance of the circuit corresponds to the first derivative $[d\phi/di]$, which equals a_1 for a short delay τ . Higher order terms define nonlinear inductor behavior that results in (for a short delay)

$$L(i) = a_1 + 2a_2 i + 3a_3 i^2 + 4a_4 i^3 + \dots$$

This nonlinear inductor response is interesting from a frequency synthesis point of view, since it can generate harmonics and subharmonics from the exciting current $i(t)$ (see, for instance Chua [4.30]).

Time-Dependent Viewpoint

In spite of the variety of different viewpoints describing hysteresis given above, some experimentally observed phenomena cannot be explained using any of them, including one particularly important phenomenon known as the magnetic after-effect. Experimentally, one observes a change in magnetization with time $M(t)$, despite the fact that the applied field H is kept constant, implying the presence of a time-dependent hysteresis loop stemming solely from $M(t)$. Therefore, the material must

contain units (single-domain grains) that respond differently over time, as if each unit had its own intrinsic delay; in this case the magnetization could be written in the form $M(t) = M_0 S(t) \ln(t)$, where $S(t)$ is called the magnetic viscosity. If the response time of each

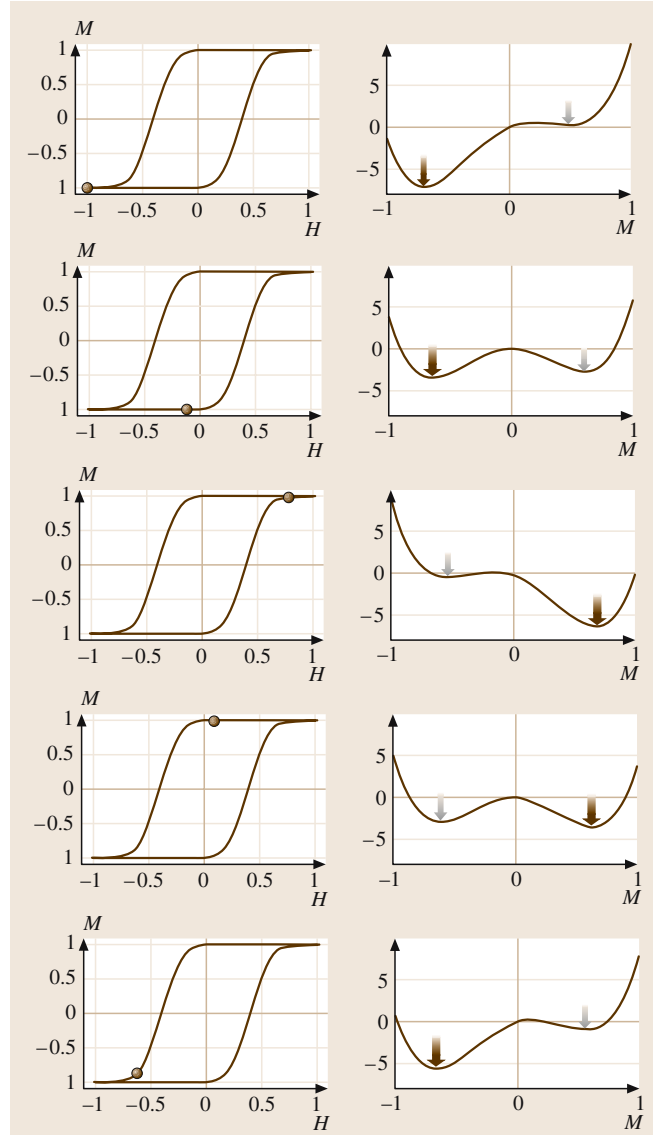

Fig. 4.5 Hysteresis loop (left) and energy as a function of magnetization (right). As the field H is varied in the hysteresis loop (as indicated by the spot ●) in a clockwise fashion, the energy changes its form and its absolute minimum (indicated by the fat arrow) moves accordingly. Hysteresis is due to asymmetric energetic behavior as the field is cycled

Fig. 4.6 Hysteresis loop as an input–output relationship. On the *left*, the magnetic field $H(t)$ and the magnetization $M(t)$ are displayed explicitly as functions of time t . On the *right*, the resulting input–output relationship (or M – H characteristic), the parametric curve $M(H)$, is shown. At the *top*, we have an output ($M(t)$) that is undelayed and proportional to the input $H(t)$, resulting in a paramagnetic (with no hysteresis) M – H characteristic. *Below*: an output $M(t)$ delayed and nonlinearly distorted version of the input $H(t)$, resulting in a hysteretic M – H characteristic. (After [4.31])

grain is considered to be of the thermal activation type, in other words it follows the Néel–Arrhenius formula (see Chapt. 51) $\tau = \tau_0 \exp(\Delta E/k_B T)$, where τ_0 is an “attempt time” to cross some energy barrier ΔE (see Fig. 4.5) at a temperature T , then the after-effect implies that we have a distribution of τ_0 and ΔE values. Calling the probability density function $g(\tau)$, and using a scaling initial magnetization M_0 , $M(t)$ is thus defined as:

$$M(t) = M_0 \int_0^{\infty} g(\tau) \exp(-t/\tau) d\tau.$$

In the simple case where we have a single response time τ^* , in other words $g(\tau) = 2\delta(\tau - \tau^*)$, $M(t)$ behaves as $M(t) = M_0 \exp(-t/\tau^*)$.

After analyzing the different aspects of the hysteresis loop, we now move on to investigate the physical processes that affect the magnetization behavior. We start with small magnetic fields H ; in other words $H < H_c$ (the coercive field). The initial magnetization curve follows Rayleigh’s law, $M(H) = \chi_0 H + \alpha_R H^2$, where χ_0 is the low-field susceptibility and α_R is the Rayleigh coefficient.

Since this law is valid for small fields, it describes reversible changes in the magnetization.

We now consider the physical region inside a material where the magnetization is oriented along some direction. Typically, when the extent of the material is smaller than the exchange length, one expects a single domain structure (which contains about 10^{12} – 10^{18} atoms, see also Fig. 4.1). For instance, a recording medium is considered to be made up of small grains that are made of single domains. As the recording density is increased, the grain size in the recording medium decreases, and if is small enough, its magnetization becomes sensitive to thermal energy – it can flip or reverse simply upon changes in temperature. This is called the superparamagnetic effect, and it traditionally limits longitudinal recording to 100 Gbit/in². This issue has recently been partially circumvented by introducing antiferromagnetic coupling between the storage layer and a stabilization layer. A thin film of ruthenium (7–9 Å thick) is deposited between the storage layer and the stabilization layer (Chapt. 51). If the extent of the magnetic material is large, one expects to have a multidomain structure separated by domain walls. This multidomain structure emerges in order to minimize the magnetostatic long-range dipolar interaction energy between the different moments existing in the different domains [4.32].

A domain is a piece of a material that is magnetized along a given direction (see Fig. 4.7). In general, a magnetic material contains many regions where the magnetization is aligned in a particular direction in order to minimize the magnetostatic energy. Regions with different magnetization orientations can be positioned close to one another, albeit separated by a boundary called a domain wall (typically containing about 10^2 – 10^3 atoms, Fig. 4.1). Saturation occurs when all of these regions align along some direction imposed by the external applied field. The width of a domain wall is equal (in CGS units) to $\pi(A/K)^{1/2}$, where A is the typical nearest neighbor Heisenberg exchange and K the typical anisotropy, meaning that it is the result of exchange and anisotropy; it is thinner for higher anisotropy or smaller exchange (in Fe it is about 30 nm, whereas in the hard material Nd₂Fe₁₄B it is only 5 nm). Its energy is equal to $4(AK)^{1/2}$. For bulk materials it is of the Bloch type (see Fig. 4.8), whereas for thin films (with thicknesses on the order of the exchange length) it is of the Néel type, with a width proportional to $[A/(2\pi M_s^2)]^{1/2}$. A single parameter $Q = 2K/M_s^2$ allows us to discriminate between simple ($Q < 1$) and complex wall profiles ($Q > 1$) [4.33].

Fig. 4.7a-d Possible domain structures and wall structures in a magnetic material. **(a)** Initial magnetic configuration with a large stray field (outside the material). In order to reduce the magnetostatic energy (and the stray field), domains form, as in a highly anisotropic material **(b)**. If n domains are formed, the magnetostatic energy is reduced by n [4.27]. In a material with small anisotropy, 45° closure domains are formed to minimize the magnetostatic energy **(c)**. As more domains are formed, more walls are also formed, until a compromise is reached since it is necessary to minimize the sum of the magnetostatic energy and the wall energies **(d)**. (After [4.29])

During a magnetization process, in a hysteresis loop cycle for instance, the irreversible jerky movements of domain walls due to local instabilities created by impurities, defects, inclusions or interactions between domain walls lead to Barkhausen noise. In devices and recording media, it is better to induce magnetization changes through rotation processes because they are less noisy.

4.1.3 Intrinsic Magnetic Properties

The induction B in a linear isotropic material is related to H through the relation $B = \mu_0(H + M)$, where μ_0 is the free space permeability and M is the magnetization of the material. Using the relation $M = \chi H$, which relates the magnetization to the applied field, one gets

$B = \mu_0(1 + \chi)H$. This leads to the definition of the total permeability $\mu = \mu_0(1 + \chi)$, which yields the constitutive relation $B(H) = \mu H$. The quantity χ is called the susceptibility. The nonlinear constitutive equations $M(H)$ and $B(H)$ apply to a general nonlinear material. Such constitutive relations are similar to the $I(V)$ characteristics of electronic devices. For a linear material, μ is generally frequency-dependent. If losses occur during the propagation of an electromagnetic wave in a material due to the absorption of magnetic energy, it is possible to extend the definition of permeability to the complex plane (as in dielectrics). Losses are attributed to peaks in the imaginary part of the permeability at the absorption frequencies [4.12]. At low frequencies, losses are attributed to domains, whereas at high frequencies, losses are attributed to rotation processes. Finally, since the permeability relates two vector quantities B and H , if we consider a linear anisotropic material (such as a linear crystal), the relation $B(H) = \mu H$ becomes $B_\alpha = \mu_{\alpha\beta} H_\beta$ (Einstein summation convention used),

Fig. 4.8 Possible domain wall shapes in a magnetic material. *Above*: the Bloch type for bulk materials, with the magnetization rotating in a vertical plane with the associated poles. *Below*: the Néel type for thin films. For these walls, the magnetization rotates in a horizontal plane when the width of the film is smaller than the exchange length. (After [4.34])

Fig. 4.9 Easy axis hysteresis loop. When the magnetic field is along the anisotropy axis (easy axis) of the material, the hysteresis loop is broadest and the magnetization jumps (switches) to $\pm M_s$ at the coercive field $\pm H_c$

and $\mu_{\alpha\beta}$ is a second-rank permeability tensor that has different components according to the relative directions of \mathbf{B} and \mathbf{H} (nine components in total, or 3^2 in three dimensions). For a nonlinear anisotropic material, we have $\mu_{\alpha\beta} = \partial B_\alpha / \partial H_\beta$.

When a material is run through a field cycle (a hysteresis loop) for the first time, the magnetization \mathbf{M} follows a path different to the $\mathbf{M}(\mathbf{H})$ lines described above. This path represents the initial magnetization, and the associated permeability is the initial permeability (Fig. 4.2). If a magnetic material is subjected to a static magnetic field \mathbf{H} and a small time-dependent field $\mathbf{h}(t)$ (alternating at frequency f) parallel to \mathbf{H} , the magnetic response is called the longitudinal permeability (at the frequency f). This kind of excitation is encountered in ferromagnetic resonance (FMR) problems (see Wigen [4.16]).

Alternatively, one can describe magnetic behavior in terms of susceptibility. This relates the magnetization to the applied field in a linear material through $\mathbf{M} = \chi \mathbf{H}$. For a nonlinear isotropic material, we have $\chi = \partial M / \partial H$, and for a nonlinear anisotropic material we have $\chi_{\alpha\beta} = \partial M_\alpha / \partial H_\beta$, with the \mathbf{M} component along the direction α and the \mathbf{H} component along β . Any jump in χ signals an important magnetic change in the material. When the temperature is decreased, the Curie temperature signals the change to ferromagnetic order from paramagnetic disorder, and the Néel temperature signals the change to antiferromagnetic order from paramagnetic disorder. Magnetic susceptibility spans several orders of magnitude (from about 10^{-5} to 10^6 cm³/mol).

The magnetization occurs along the direction that minimizes the sum of the magnetic anisotropy energy

Fig. 4.10 Hard axis hysteresis loop. When the magnetic field is along the hard axis of the material, the hysteresis loop is the thinnest and the magnetization rotates smoothly from one value to another between $\pm H_K$ (the anisotropy field)

and the Zeeman energy provided by the applied field. Since the hysteresis loop changes its shape as we vary the angle of the applied field, at some point it reaches its largest width. The field then indicates the easy axis direction (also called the anisotropy axis). The extremum value of the magnetic field is the coercive field $\pm H_c$, where the magnetization (switches) jumps (see Fig. 4.9) to its saturation value $\pm M_s$.

Alternatively, let us consider the direction along which it takes most effort to align the magnetization. This is easily determined as the field direction where the hysteresis loop when it is narrowest (see Fig. 4.10). The point at which the slope changes dramatically gives the value of the anisotropy field $\pm H_K$.

Crystals are generally anisotropic because their microscopic structures are not the same in all directions. Hence, the properties (including magnetic properties) will change with the orientation of the crystal. Indeed, there will be special directions along which the magnetization prefers to point. This means that some kind of energy will be minimized when the magnetization settles along these directions: the anisotropy energy. As well as being inherent to many crystal structures, anisotropy can also be induced by an external field, a change of symmetry (for example at the surface with respect to bulk) or mechanical deformation. Microscopically, anisotropy originates from spin-orbit coupling. Coercivity increases with anisotropy; in other words the hardness increases with anisotropy (Fig. 4.11). The anisotropy energy can be evaluated from the hysteresis loop by determining the loop for various angles between the applied field and the easy axis. In general, it

is given by an expansion of the form $\sum_{\alpha,\beta} K_{\alpha\beta} M_{\alpha} M_{\beta} + \sum_{\alpha,\beta,\gamma,\delta} K_{\alpha\beta\gamma\delta} M_{\alpha} M_{\beta} M_{\gamma} M_{\delta} \dots$, where $K_{\alpha\beta}$, $K_{\alpha\beta\gamma\delta}$ are the anisotropy coefficients (second- and fourth-order respectively), and M_{α} , M_{β} are the components (direction cosines) of the normalized magnetization (by the saturation magnetization M_s). α, β, γ are the indices along the crystal x, y, z axes. This means that the norm of \mathbf{M} , $|\mathbf{M}| = (M_x^2 + M_y^2 + M_z^2)^{1/2} = 1$ in this case.

The anisotropy energy of a crystal with a single dominant axis (such as hexagonal – like cobalt, tetragonal and rhombohedral crystals) is called uniaxial. To the lowest approximation, it is given by $K_1 \sin^2 \theta$, where K_1 is the anisotropy strength, and the angle θ is the angle between the magnetization and the easy axis. The next lowest approximation allows fourth-order terms to be added to the $K_1 \sin^2 \theta$ term. In hexagonal crystals, the fourth-order term is of the form $K_2 \sin^4 \theta$. Rhombohedral symmetry allows two fourth-order terms of the form $K_2 \sin^4 \theta + K_4 \cos \theta \sin^3 \theta \cos 3\phi$. In tetragonal crystals, the fourth-order terms are of the form $K_2 \sin^4 \theta + K_4 \cos \theta \sin^4 \theta \cos 4\phi$. The easy axis is taken to be along the z -axis, the angle ϕ is the magnetization polar angle in the xy -plane, and θ is the azimuthal angle.

The anisotropy energy for a crystal with two dominant axes (including monoclinic, triclinic and orthorhombic crystals) is called biaxial. This means that two anisotropy directions exist and are competing. Some other cases are given below (see also Table 4.1 for other definitions).

Cubic Anisotropy

The anisotropy energy for the most symmetric crystals, cubic crystals, is given by $K_1 (M_1^2 M_2^2 + M_1^2 M_3^2 + M_2^2 M_3^2) + K_2 M_1^2 M_2^2 M_3^2$ (the energy is to the sixth order). Here the coefficients M_1, M_2, M_3 are the components of the normalized magnetization with respect to the crystal axes. That is, $M_1 = \sin \theta \cos \phi$, $M_2 = \sin \theta \sin \phi$, $M_3 = \cos \theta$. The easy axis, as above, is taken to be along the z -axis, and the angle ϕ is the polar angle in the xy -plane.

Helical Anisotropy

In a magnetic wire, the magnetization may prefer to lie radially in a plane perpendicular to the wire axis, resulting in a radial easy axis (radial anisotropy). If it lies along the tangents to circles that lie on planes perpendicular to the wire axis, then we have circular anisotropy. However, if it lies in a plane tangent to the lateral surface of the wire (parallel to the wire axis) and it makes

an angle that is different to 0° or 90° degrees with any plane perpendicular to the wire axis, we then have helical anisotropy.

Shape Anisotropy

A finitely sized magnetic body (an ellipsoidal shape is assumed here for simplicity) possessing uniform magnetization \mathbf{M} (represented by its components M_{α}) contains a magnetic energy (also called the magnetostatic energy) given by $2\pi N_{\alpha\beta} M_{\alpha} M_{\beta}$ (Einstein summation). The $N_{\alpha\beta}$ coefficients are the demagnetization coeffi-

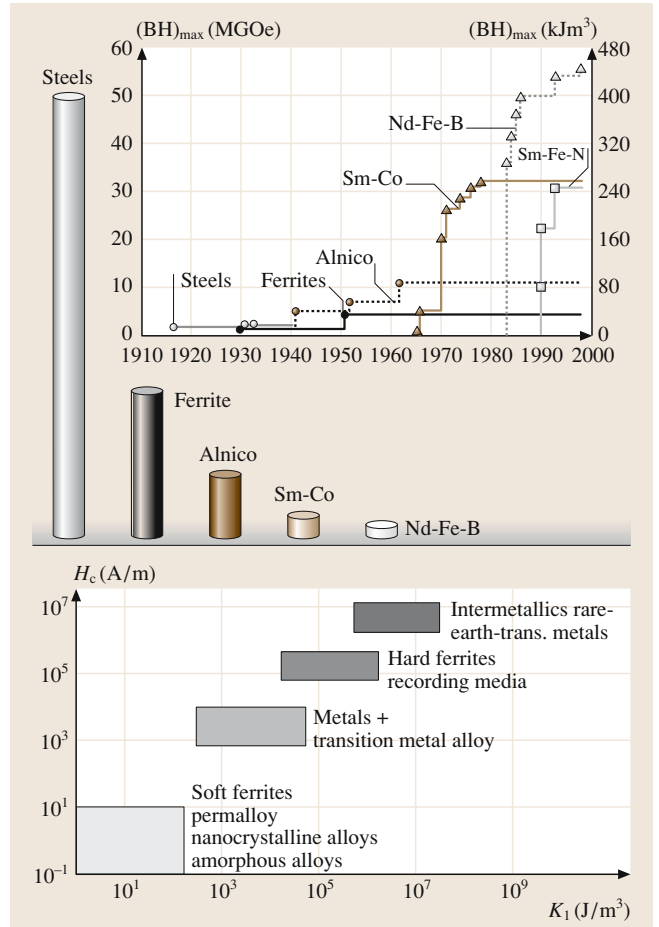

Fig. 4.11 In the upper graph, the development of hard materials for permanent magnets is associated with the value of the energy density $(BH)_{\max}$. In the middle, the progress is indicated by equivalent volume change for a fixed energy density. In the lower graph, the correlations between the coercivity H_c and the anisotropy coefficient K_1 for various materials, their magnetic hardnesses and corresponding applications. (After [4.17, 22], see Table 4.1)

cients of the body, which are determined by its shape. The origin of this terminology is its resemblance to the familiar anisotropy energy of the form $K_{\alpha\beta}\mathbf{M}_\alpha\mathbf{M}_\beta$ (Einstein summation). If a magnetic material contains N moments (atoms, ions or molecules, each carrying a moment μ_i), the energy originating from the dipolar coupling energy between the different moments is written as:

$$W_{\text{dip}} = \frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N \frac{\mu_i \cdot \mu_j}{r_{ij}^3} - \frac{3(\mu_i \cdot \mathbf{r}_{ij})(\mu_j \cdot \mathbf{r}_{ij})}{r_{ij}^5}$$

μ_i and μ_j are two moments ($i \neq j$) in the material separated by a distance \mathbf{r}_{ij} . This energy can only be represented by constant coefficients ($N_{\alpha\beta}$) if the body has an ellipsoidal shape. Hence one can write $W_{\text{dip}} \approx 2\pi N_{\alpha\beta} \mathbf{M}_\alpha \mathbf{M}_\beta$ (Einstein convention), where the magnetization \mathbf{M} is the sum of all individual moments μ_i .

Surface Anisotropy

A finitely sized magnetic body with a bulk anisotropy (which is not too large) will realign the magnetization close to its surface in order to minimize the magnetostatic energy. In other words, the body has a surface anisotropy that is different from the bulk one. This originates from an abrupt change of symmetry at the interface between the bulk and free surface.

Anisotropy From Demagnetization

The demagnetization energy is expressed using coefficients that describe the demagnetization field \mathbf{H}_d inside a finitely sized material, created by a bulk magnetization acting against an applied external magnetic field. The components of the demagnetization field (in the ellipsoidal case) are given by (with Einstein summation) $[\mathbf{H}_d]_\alpha = -2\pi N_{\alpha\beta} \mathbf{M}_\beta$ (much like the depolarization field in the electrical case). Constant coefficients ($N_{\alpha\beta}$) are only valid when the body has an ellipsoidal shape. The coefficients depend on the geometry of the material. There are usually three positive coefficients along three directions N_{xx} , N_{yy} and N_{zz} (assuming the off-diagonal terms are all 0) in simple geometries such as wires, disks, thin films and spheres. All three coefficients are positive and smaller than 1, and their sum is 1. For a sphere, all three of the coefficients are equal to 1/3. For a thin film (or a disk) they are given by 0,0,1 when the z -axis is perpendicular to a film (or the disk) lying in the xy -plane. For a cylindrical wire of infinite length that has its axis aligned with the z -direction, the values are 1/2,1/2,0.

4.1.4 Traditional Types of Magnetism and Classes of Magnetic Materials

The main traditional types of magnetism are ferromagnetism, antiferromagnetism, ferrimagnetism, paramagnetism and diamagnetism. However, other types are also described in the review by Hurd [4.10], and with the expected advances in materials science we may expect to encounter other new classes in the future, as described in Sect. 4.2 of this work, dedicated to unconventional magnetic types (Table 4.1).

A ferromagnet is an assembly of magnetic moments interacting with a positive exchange integral that minimize their energies by adopting a common parallel configuration resulting in a net large value of total magnetization. Such a definition is valid for localized magnetism but not for itinerant ferromagnets (such as the transition metals Fe, Ni and Co), since one does not have distinct localized moments that can define an exchange integral in these materials. A ferromagnetic material (itinerant or localized) displays a characteristic hysteresis curve and remanence ($\mathbf{M} \neq 0$ for $\mathbf{H} = 0$) when one varies the applied magnetic field. When heated, the material generally loses this ordered alignment and becomes paramagnetic at the Curie temperature. Ferromagnets are usually metallic, but there are ferromagnetic insulators, such as CrBr_3 , EuO , EuS and garnets [4.27, 35].

An antiferromagnet is made up of an assembly of magnetic moments interacting with a negative exchange integral that minimize their energies by adopting an antiparallel configuration. Again, such a definition is not valid for itinerant antiferromagnets (such as Cr and Mn) since one does not have distinct localized moments and so an exchange integral cannot be defined. The net total magnetization is zero, so we do not get hysteresis. In the localized magnetism case, it is possible to consider the entire crystal as made of two interpenetrating sublattices containing moments that are all parallel inside each sublattice but where the magnetizations from all sublattices cancel each other out. When heated, the material generally loses this alternately ordered alignment and becomes paramagnetic at the Néel temperature. Oxides are generally antiferromagnetic insulators (an exception is EuO) [4.29, 35].

It is possible to have intermediate order between ferromagnets and antiferromagnets; this occurs in the ferrimagnets used in microwave devices [4.16]. In the localized case, one considers the crystal as being made of two sublattices (as in the case of an antiferromagnet), with total magnetizations that oppose one another. How-

Fig. 4.12a–d Shown *above* is the magnetic moment arrangement in an ferrimagnet. The total net magnetization is nonzero. *Below*: a comparison of the magnetic arrangements between a ferromagnet (a), an antiferromagnet (b), a ferrimagnet (c) and a weak ferromagnet (d). (After [4.29])

ever, the magnitude of each magnetization is different, resulting into a net total magnetization, in contrast to an antiferromagnet.

Another intermediate case is a canted antiferromagnet, also called a weak ferromagnet. This is an assembly of magnetic moments that alternate in direction making a small inclination in the direction of the moment (canting). The small angle (Fig. 4.12d) between two neighboring moments results in a small ferromagnetic moment. Canting results from a Dzyaloshinski–Moriya exchange interaction (see Sect. 4.2.1 and [4.24, 35]). In the absence of that interaction, the moments are aligned antiparallel, like in a perfect antiferromagnet.

If we have an assembly of magnetic moments oriented at random with a zero total magnetic moment, we call it a paramagnet. Such materials do not display hysteresis or remanence when one varies the applied magnetic field. The magnetic field simply imposes some alignment onto the randomly oriented moments. For a paramagnet, the susceptibility χ is positive and many orders of magnitude smaller than for ferromagnets, and it behaves as $1/(T - T_c)$ where T_c is the Curie temperature. Some materials never order magnetically, not even at low temperatures (which implies that $T_c = 0$ K), where order prevails. On the other hand, some materials, known as superparamagnetic, show no hysteresis or remanence but have $T_c = \infty$. This does not mean that they are always ordered, but their individual moment is so large (a classical moment corresponds to a quantum angular momentum $J = \infty$, resulting in $T_c = \infty$) that it takes an infinite temperature to destroy it completely [4.27, 35].

A material that combats the influence of a magnetic field by trying to maintain zero induction ($B = 0$) while the field is applied is known as diamagnetic (copper is diamagnetic and superconductors are perfect diamagnets). The term diamagnetic is actually a misnomer, since “dia” means across, implying that the field propagates across the material, whereas the opposite is true. When a diamagnetic substance such as a silicon crystal is placed in a magnetic field, the magnetization vector \mathbf{M} in the material points in the opposite direction to the applied field. A negative susceptibility can be interpreted as the diamagnetic substance trying to expel the applied field from itself. A substance exhibits diamagnetism whenever the constituent atoms in the material have closed subshells and shells. This means that each constituent atom has no permanent magnetic moment in the absence of an applied field. Typical diamagnetic materials include covalent crystals and many ionic crystals, because the constituent atoms in these substances

Table 4.3 Examples of soft magnetic materials and their hierarchy according to the saturation magnetostriction coefficient λ_s . The main composition is successively based on Fe, NiFe and finally Co. μ_{\max} is the maximum differential permeability and H_c is the coercive field. $\text{Fe}_{80}\text{B}_{20}$ is also called Metglass 2605. $\text{Fe}_{40}\text{Ni}_{40}\text{P}_{14}\text{B}_6$ is also called Metglass 2826. The highest μ_{\max} is attained by $(\text{Fe}_{0.8}\text{Ni}_{0.2})_{78}\text{Si}_8\text{B}_{14}$, reaching 2×10^6 after annealing [4.35]

Alloy	H_c (mOe)	μ_{\max} at 50 Hz	Saturation magnetostriction coefficient
$\text{Fe}_{80}\text{B}_{20}$	40	320 000	$\lambda_s \approx 30 \times 10^{-6}$
$\text{Fe}_{81}\text{Si}_{3.5}\text{B}_{13.5}\text{C}_2$	43.7	260 000	
$\text{Fe}_{40}\text{Ni}_{40}\text{P}_{14}\text{B}_6$	7.5	400 000	$\lambda_s \approx 10 \times 10^{-6}$
$\text{Fe}_{40}\text{Ni}_{38}\text{Mo}_4\text{B}_{18}$	12.5–50	200 000	
$\text{Fe}_{39}\text{Ni}_{39}\text{Mo}_4\text{Si}_6\text{B}_{12}$	12.5–50	200 000	
$\text{Co}_{58}\text{Ni}_{10}\text{Fe}_5(\text{Si}, \text{B})_{27}$	10–12.5	200 000	$\lambda_s \approx 0.1 \times 10^{-6}$
$\text{Co}_{66}\text{Fe}_4(\text{Mo}, \text{Si}, \text{B})_{30}$	2.5–5	300 000	

have no unfilled sub-shells. Since the diamagnetic material tries to minimize the effect of \mathbf{H} , it expels field lines – a phenomenon that can be exploited in magnetic levitation. A superconductor is a perfect diamagnet, and a metal exposed to high frequencies is partially diamagnetic, since the applied field can only penetrate it to skin depth. The susceptibility χ is constant for a diamagnet (it does not vary with temperature) and is slightly negative. Superconductors have $\chi = -1$ (below critical temperature), whereas semiconductors have the following values of susceptibility (in cm^3/mol) at room temperature: Si, -0.26×10^{-6} ; Ge, -0.58×10^{-6} ; GaAs, -1.22×10^{-6} ; as given by Harrison [4.36].

Materials with a relatively small coercive field (typically smaller than 1000 A/m), as preferred in transformer cores and magnetic read heads, are called soft magnetic materials. Most (but not all) simple metals, transition metals and their compounds are soft. Permalloys, amorphous and nanocrystalline alloys and some ferrites are soft. Amorphous materials are soft because their disordered structure does not favor any direction (no anisotropy energy), whereas nanocrystals possess anisotropy over a short length scale (although it can be larger than its bulk counterpart). Softness is also measured by the maximum permeability attainable (see Table 4.3 of soft elements).

On the other hand, a material with a relatively large coercive field (typically larger than 10 000 A/m), as preferred in permanent magnets, motors and magnetic recording media (disks and tapes), is called a hard magnetic material. This means that stored data is not easily lost since a large field is required to alter the magnitude of magnetization. Most (but not all) rare-earth metals, their compounds and intermetallics are hard. There are also hard ferrites. Permanent magnets are used in power systems (in power relays), motors and audio/video equipment (such as headphones, videotapes); see Table 4.1 and Fig. 4.11.

Ferrites are ferrimagnetic ceramic-like alloys. During the early development of ferrites, the compositions of all ferrites could be described as FeOFe_2O_3 . However, more modern ferrites are better described as MOFe_2O_3 , where M is a divalent metal (note that the Fe in Fe_2O_3 is trivalent). Ferrites are used in microwave engineering and recording media due to their very low eddy current losses [4.12] and the fact that they operate over a large frequency interval (kHz to GHz). The ratio of the resistivity of a ferrite to that of a typical metal can reach as high as 10^{14} . They are made by sintering a mixture of metallic oxides MOFe_2O_3 where $\text{M}=\text{Mn}, \text{Mg}, \text{Fe}, \text{Zn}, \text{Ni}, \text{Cd}...$ Ferrite read heads are however limited to

frequencies below 10 MHz as far as switching is concerned, and this is why several new types of read head (thin films, AMR, GMR, spin valves, magnetic tunnel junctions) have been or are being developed in order to cope with faster switching (Chapt. 51). Other conventional magnetic materials similar to ferrites include spinels and garnets, as described below.

Spinel

Spinel are alloys with the composition $(\text{MO})_x(\text{MO})_{1-x}\text{Fe}_2\text{O}_3$ (a generalization of the ferrite composition), that have the structure of MgAl_2O_4 (which provides the origin of the word spinel) [4.16].

Garnets

Garnets are oxides that have compositions related to the spinel family, of the form $(3 \text{M}_2\text{O}_3, 5 \text{Fe}_2\text{O}_3)$, that crystallize into the garnet cubic structure $[\text{Ca}_3\text{Fe}_2(\text{SiO}_4)_3]$. They are ferromagnetic insulators of general formula $\text{M}_3\text{Fe}_5\text{O}_{12}$, where M is a metallic trivalent ion ($\text{M}=\text{Fe}^{3+}$ for example). Garnets have been used in memory bubble technology, lasers and microwave devices (because their ferromagnetic resonance linewidth with respect to the field is small, on the order of a fraction of an Oersted, when the resonance frequency is several tens of GHz [4.16].), especially those of general formula $\text{M}_3\text{Ga}_5\text{O}_{12}$. For instance, when produced as a thin film a few microns thick, $\text{Gd}_3\text{Ga}_5\text{O}_{12}$, called GGG (gadolinium gallium garnet), exhibits perpendicular anisotropy with domains (bubbles) that have up or down magnetization (perpendicular with respect to the film plane). Thus, a bit can be stored in a bubble and can be controlled using a small magnetic field. GGG is considered to be one of the most perfect artificially made crystals, since it can be produced with extremely few defects (less than 1 defect per cm^2). Another nomenclature, called the [cad] notation, is used with rare-earth iron garnets of general formula $\text{X}_3\text{Y}_2\text{Z}_3\text{O}_{12}$. This notation means: dodecahedral (c site is surrounded by 12 neighbours and represented by element X); octahedral (a site is surrounded by 8 neighbours and represented by element Y); and tetrahedral (d site is surrounded by 4 neighbours and represented by element Z). The most important characteristic of these garnets is the ability to adjust their compositions and therefore their magnetic properties according to selected substitutions on the c, a or d sites. The element X is a rare earth, whereas Y and Z are Fe^{3+} . The magnetization is changed by placing nonmagnetic ions on the tetrahedral d site: increasing the amount of Ga^{3+} , Al^{3+} , Ge^{4+} , or Si^{4+} will decrease the magnetization. On the other hand, increas-

ing the amount of Sc^{3+} or In^{3+} at the octahedral a site will increase the magnetization. Ion substitution can also be used to tailor other magnetic properties (including anisotropy, coercivity and magnetostriction). Garnets are typically grown using liquid phase epitaxy at a growth speed that easily reaches a micron in thickness in one minute, and a very high yield is achieved. These materials have not only been used in

bubble materials but also in magneto-optical displays, printers, optical storage, microwave filters and integrated optics components. Despite all of these attractive properties, their easy tunabilities and very high yields, problems soon arose with the limited access times of bubble memories, since the switching frequency was found to be limited to less than about 10 MHz [4.16] (Chapt. 51).

4.2 Unconventional Magnetism

4.2.1 Conventional and Unconventional Types of Exchange and Coupling in Magnetic Materials

In conventional magnetic materials, the strength of the magnetic interactions between two neighboring localized moments i and j (as in atoms/ions/molecules and rare-earth solids) is described by a direct exchange interaction. The latter is essentially a Coulomb (electrostatic) interaction between the electrons at the i and j sites. The word exchange is used because the corresponding overlap integral describing this interaction involves wavefunctions with permuted (exchanged) electron coordinates (in order to respect the Pauli exclusion principle). The exchange energy between sites i and j is given by $-A_{ij}\mathbf{M}_i\cdot\mathbf{M}_j$ where \mathbf{M}_i and \mathbf{M}_j are, respectively, the magnetization at the i and j sites [4.29]. When $A_{ij} > 0$, the energy is minimized when the moments are parallel, and when $A_{ij} < 0$ an antiparallel configuration of the moments is favored. The energy arising from exchange over a distance r in the continuum limit is approximately AM^2/r^2 .

The RKKY (Ruderman–Kittel–Kasuya–Yoshida, [4.27]) oscillatory interaction occurs between two localized moments mediated by a surrounding electron gas. It varies in 3-D systems as $\cos(2k_F r)/r^3$, where r is the distance between the moments and k_F is the Fermi wavevector of the electron gas. It was recently discovered that a counterpart of the RKKY interaction exists in 2-D between two magnetic thin films separated by a metallic spacer [4.37]. The RKKY-like interaction between the two magnetic films across a metallic spacer is oscillatory with respect to the spacer thickness z . Thus it becomes possible to decide to couple the magnetic films positively (ferro) or negatively by changing the thickness z of the metallic spacer (see Fig. 4.1 for typical lengths). This is extremely useful for thin film devices (see Chapt. 51 and Table 4.1).

The Dzyaloshinski–Moriya exchange interaction is a vectorial exchange interaction between two neighboring localized moments (\mathbf{M}_i and \mathbf{M}_j) of the form $D_{ij}\mathbf{M}_i\times\mathbf{M}_j$, which contrasts with the scalar ordinary exchange interaction of the form $A_{ij}\mathbf{M}_i\mathbf{M}_j$. This cants (producing a small inclination between) two neighboring antiferromagnetic moments that are usually antiparallel, resulting in weak ferromagnetism. This is due to asymmetric spin-orbit effects [4.24].

Present interest is focused on magnetic thin films and their interactions. Information storage, sensing, spintronics, quantum computing and other applications of magnetic thin film devices are the main spur to understand the nature and extent of magnetic exchange interactions and coupling effects as well as those that arise between magnetic 2-D layers in order to tailor appropriate devices. Novelty is expected since the device size is comparable to the interaction length (Fig. 4.1).

The coupling strength of the interaction between two neighboring magnetic films i and j can be modeled by a factor J_{ij} . This is similar to the exchange integral A_{ij} between two neighboring localized moments, but it involves entire layers generally made from itinerant magnets and not the single moments used with A_{ij} . The exchange interaction is of the form $J_{ij}\mathbf{M}_i\cdot\mathbf{M}_j$, where \mathbf{M}_i and \mathbf{M}_j are the magnetizations per unit surface of films i and j . The main interest in J_{ij} lies in the fact that its range is longer in reduced dimensions (1-D and 2-D) than in 3-D (for instance, an RKKY-like interaction between two magnetic films across a metallic spacer is oscillatory with a longer range than it is in 3-D, since it varies like $1/r^2$ instead of $1/r^3$), and its physics is entirely different from the standard RKKY interaction between localized moments [4.37]. The sign of the interaction depends on the thickness of the metallic spacer. Other types of exchange exist between films, such as biquadratic or higher order with a generalized Heisenberg form $I_{ij}[\mathbf{M}_i\mathbf{M}_j]^n$ where $n \geq 2$ and I_{ij} is a coupling constant

Fig. 4.13 Coupling and exchange between magnetic layers separated by a nonmagnetic (metallic or insulating) spacer. The *top* drawing shows ferromagnetic coupling arising from pinholes that exist across the spacer, whereas the *middle* drawing shows exchange-coupled layers that might be ferro- (*left*) or antiferromagnetic (*right*), depending on the (generally metallic) spacer thickness. Finally, the *bottom* drawing schematizes magnetostatic dipolar coupling between the top and bottom layers. (After [4.10].)

that is a function of n and the separation between the films (Table 4.1).

Interactions between two ferromagnetic (or other types of magnetic) films are not limited to metallic spacers; they can occur across an insulating or semiconducting spacer (Fig. 4.13). Magnetic pinholes generally mediate direct ferromagnetic coupling between neighboring multilayers. They are viewed as shorts across the insulating or semiconducting spacer. Néel proposed that conformational roughness (the orange-peel model, see *Schulthess and Butler* [4.38] for instance) at interfaces can result in ferromagnetic coupling for a moderate thickness of spacer material. Magnetostatic dipolar coupling occurs between the roughness features or between domain walls in the two magnetic layers. In this case, stray flux fields from walls in one film can influence the magnetization reversal process in the other. The Slonczewski loose-spin model (see Table 4.1, related to exchange and coupling in multilayers) is based on the change in angular momentum experienced by spin-polarized electrons tunneling across an insulating spacer, resulting in a magnetic exchange coupling. The magnitude and sign of the coupling oscillates depending on the interfacial barrier properties ([4.10] and Table 4.1).

In the absence of a spacer, the exchange energy per unit surface area of ferromagnetic and antiferromagnetic films gives rise to a new phenomenon called exchange

bias (the shift of the hysteresis curve of the ferromagnetic film, see entry in Table 4.1). An important consequence of this bias is a pinning-down of the direction of the ferromagnetic moment, which is used in low-noise read heads because it hinders noisy (jerky) domain wall motion (Chapt. 51). Exchange bias is also called anisotropic exchange, and is still poorly understood from a fundamental level despite the fact it was discovered more than 50 years ago.

4.2.2 Engineering and Growth of Thin Magnetic Films

A magnetic film is considered to be thin if its thickness is smaller than the (bulk-defined) exchange length; in other words its thickness corresponds to the spatial extent of a single domain [4.10]. Magnetic thin films possess very attractive and distinct physical properties with respect to their bulk counterparts. For instance, reduced dimensionality, coordination and symmetry lead to magnetocrystalline anisotropy energies that are two or three orders of magnitude larger than for the bulk (the phenomenon of quenching of the orbital angular momentum – as seen in transition metal ions – is absent, see *Kittel* [4.27]). Saturation magnetization M_s is also enhanced with respect to bulk, since the effective Bohr magneton number n_B per atom/molecule is larger at lower dimensions (for instance in nickel clusters n_B can reach 1.8, whereas in the bulk it is only 0.6). Couplings are also enhanced in thin films, as in the case of the RKKY-like interaction across a metallic spacer. Coupling between two magnetic layers across a semiconducting spacer or an insulator leads to entirely new interactions such as those described by the Slonczewski loose-spin model or the Bruno quantum interference model. New couplings also arise, such as anisotropic exchange or exchange bias between a ferro and an antiferromagnetic layer, and new types of multilayers can be made (spring magnets) by alternating hard and soft thin films (Table 4.1).

When we consider the growth of magnetic materials as thin films, we should recall that these films possess distinct physical properties with respect to the materials used in conventional microelectronics, such as surface energies. The free energies γ of the surface and the interface play dominant roles. They determine the growth modes in thermal equilibrium; the morphology of material B grown on material A depends on the balance between the free surface energies of the substrate, the overlayer and the interface [4.10]. Transition metal-based magnetic materials exhibit a relatively

Table 4.4 Surface energies γ (in J/m²) for magnetic and nonmagnetic materials, listed with respect to their atomic number for the low-energy cleavage surface. These are approximate values, which are difficult to measure in general and depend on surface orientation and reconstruction [4.10]

Magnetic metal γ (J/m ²)	Cr 2.1	Mn 1.4	Fe 2.9	Co 2.7	Ni 2.5	Gd 0.9				
Transition metal γ (J/m ²)	Ti 2.6	V 2.9	Nb 3.0	Mo 2.9	Ru 3.4	Rh 2.8	Pd 2.0	Ta 3.0	W 3.5	Pt 2.7
Simple or noble metal γ (J/m ²)	Al 1.1		Cu 1.9		Ag 1.3		Au 1.6			
Semiconductor γ (J/m ²)	Diamond 1.7		Si 1.2		Ge 1.1		GaP 1.9		GaAs 0.9	
Insulator γ (J/m ²)	LiF 0.34		NaCl 0.3		CaF ₂ 0.45		MgO 1.2		Al ₂ O ₃ 1.4	

high surface energy, owing to their partially filled d shells. Noble metal substrates have smaller surface energies, and insulating substrates even less. Additionally, when one performs epitaxial growth, another concern is lattice-matching the different underlayers, as displayed in Table 4.4 and Table 4.5, along with typical quantities of interest in representative magnetic materials.

4.2.3 Electronic Properties: Localized, Free and Itinerant Magnetism and Spin-Polarised Band Structure

Building a working device requires an understanding of not only magnetic properties but also electronic properties and their interplay. We expect that new devices will be constructed from a variety of magnetic (conventional and unconventional) materials as well as others already known in microelectronics. Insulating oxides (except EuO) and rare-earth compounds with well-localized external-shell f electrons are solid state

materials with atom-like magnetism. Magnetic atoms, ions and molecules or associated with well-defined localized orbitals and individual moments arising from orbital, spin or total angular momentum. When these moments get close to one another, as in the solid state, they interact as defined by Heisenberg: $A_{ij}\mathbf{M}_i \cdot \mathbf{M}_j$ [4.29]. The latter is altered by the presence of the surrounding free-electron gas. Therefore we must understand magnetism in a free-electron gas, its counterpart arising from localized moments, and finally its nature when we have the hybrid case (itinerant magnetism), which occurs in a transition metal (free s and localized d electrons). This problem is very complicated, and so we will rely upon a “one-electron approximation” of band structure, and more precisely spin-polarized band structure [4.11].

In a free-electron gas, one can assume independent noninteracting electrons, so many-electron and nonlocal effects (arising from exchange) do not need to be taken into account. Magnetism in this case is due to individual electron spins and it is straightforward to establish that so-called Pauli paramagnetism holds [4.27]. In addition,

Table 4.5 Lattice-matched combinations of magnetic materials, substrates and spacer layers. There are two main groups of lattice-matched systems with lattice constants close to 4.0 Å or 3.6 Å respectively, after making 45° rotations of the lattice or doubling the lattice constant (After *Himpsel et al.*[4.10] with minor editing)

First group					
Magnetic metal $2^{1/2}a$ (Å) (a (Å))	Cr (bcc) 4.07 (2.88)	Fe (bcc) 4.05 (2.87)	Co (bcc) 3.99 (2.82)		
Simple or noble metal a (Å)	Al 4.05	Ag 4.09	Au 4.07		
Semiconductor $a/2^{1/2}$ (Å) (a (Å))	Ge 3.99 (5.65)	GaAs 4.00 (5.65)	ZnSe 4.01 (5.67)		
Insulator a (Å) (a/2 ^{1/2} (Å))	LiF 4.02 (2.84)	NaCl 5.65 (3.99)	MgO 4.20 (2.97)		
Second group					
Material a (Å)	Fe (fcc) 3.59	Co (fcc) 3.55	Ni (fcc) 3.52	Cu 3.61	Diamond 3.57

orbital effects give rise to Landau diamagnetism. The spin-polarized density of states is shifted by the field contribution $\pm\mu_B B$ depending on the spin orientation with respect to the field B . In the free-electron Pauli case, the magnetization can be evaluated (at $T = 0$ K) from

$$\begin{aligned} M &= \mu_B (N_{\uparrow} - N_{\downarrow}) \\ &= \frac{\mu_B}{2} \int_{-\mu_B B}^{E_F} dE N(E + \mu_B B) \\ &\quad - \frac{\mu_B}{2} \int_{\mu_B B}^{E_F} dE N(E - \mu_B B) \end{aligned}$$

which yields $M \approx \mu_B^2 N(E_F) B$, where μ_B is the Bohr magneton, $N(E)$ is the free electron and $N_{\uparrow\downarrow}(E)$ the spin-polarized density of states. The contribution from Landau (orbital) diamagnetism is a lot more complicated to evaluate, but it is exactly minus one third of the paramagnetic expression [4.27].

Fig. 4.14 Spin-polarized density of states for bcc Fe and fcc Ni. The bands for the spin up electrons are separated from the spin down band by the exchange splitting energy. The method used is superior to the **LSDA** method which yields a noisy density of states. The authors call it **LDA+DMFT** (local density approximation + dynamical mean field theory). (After [4.39])

States derived from the 3d and 4s atomic levels are responsible for the physical properties of transition metals (itinerant magnets). The 4s electrons are more spatially extended (have a higher principal quantum number) and determine (for instance) the compressibility, whereas the 3d states determine the magnetic properties. The 3d electrons still propagate throughout the material; hence the term itinerant magnetism. The spin-polarized band structure of a transition metal is different to that of a conventional electronic material (see Fig. 4.14 and Fig. 4.15 for the electronic band structures of iron, nickel and cobalt and Table 4.6 for their physical properties).

Many metals have an odd number of electrons (in the atomic state), and so one would expect them to be magnetic due to their unpaired spins; however, only five of them are actually magnetic (Cr, Mn, Fe, Ni and Co, which are all transition metals with s–d hybridization). Note that copper is diamagnetic, with $\chi = -0.77 \times 10^{-6} \text{ cm}^3/\text{mol}$ at room temperature; Fe, Ni and Co are ferromagnets; whereas Cr and Mn are antiferromagnets.

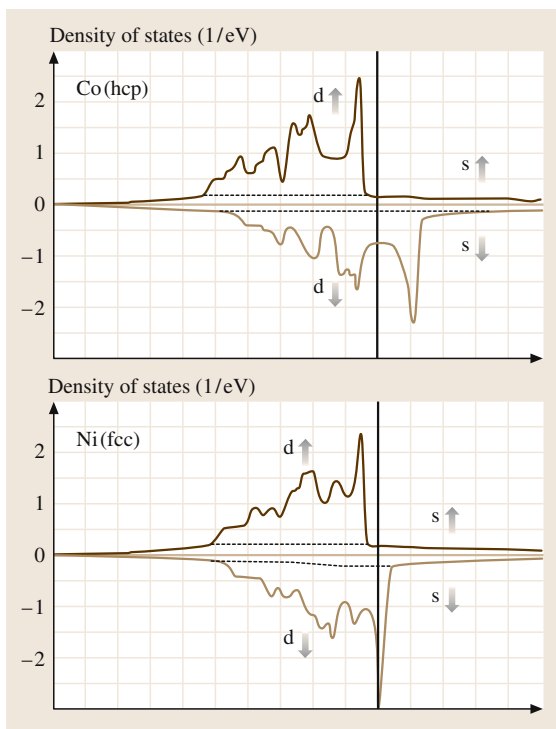

Fig. 4.15 Symmetric double-sided representation of the spin-polarized density of states for Co and Ni (obtained with the LMTO method or linearized muffin-tin orbitals), with the Fermi level indicated. (After [4.40])

Fig. 4.16 Exchange splitting versus the magnetic moment (in Bohr magnetons μ_B per atom) in 3d transition metals. The diagonal line is 1 eV/ μ_B , and the magnetic moment values are given for the element (in the atomic state) and the corresponding crystal. (After [4.10])

It is not straightforward to model magnetism and related properties in transition metal alloys due to the itinerant nature of the electrons. In solids, magnetism arises mainly from electrostatic (Coulomb) electron–electron interactions, namely the exchange interactions, and in magnetic insulators these can be described rather simply by associating electrons with particular atomic

Table 4.6 Fundamental magnetic properties of the transition metals Fe, Co and Ni [4.35]. Note that the domain wall thicknesses and energies are approximate

Magnetic property	Fe	Co	Ni
n_B at $T = 0$ K (in Bohr magnetons)	2.22	1.72	0.62
M_s at 300 K (in 10^6 A/m)	1.71	1.40	0.48
Exchange energy A (meV)	0.015	0.03	0.020
Curie temperature (K)	1043	1404	631
Anisotropy K_1 (J/m^3) at 300 K	4.8×10^4	45×10^4	-0.5×10^4
Lattice spacing (nm)			
a	0.29	0.25	0.35
c		0.41	
Domain wall thickness			
• in nm	40	15	100
• in lattice parameters	138	36	285
Domain wall energy (J/m^2)	3×10^{-3}	8×10^{-3}	1×10^{-3}

sites so that Heisenberg exchange $A_{ij}\mathbf{M}_i \cdot \mathbf{M}_j$ can be used to describe the behavior of these systems. In metallic systems it is not possible to distribute the itinerant electrons in this way, and such simple pairwise interactions between sites cannot be defined. Metallic magnetism is a complicated many-electron effect that has required significant effort over a long period to understand and describe it [4.10]. A widespread approach is to map this problem onto one involving independent electrons moving in the fields set up by all of the other electrons. It is this aspect that gives rise to the spin-polarized band structure that is often used to explain the properties of metallic magnets (such as the non-integer values of multiples of the Bohr magneton μ_B). In addition, compositional structure plays a major role in itinerant magnetism. Consider for instance the ordered Ni–Pt alloy. This is an antiferromagnet, whereas its disordered counterpart is ferromagnetic. It can be said that itinerant magnetism occurs between two extreme limits: the localized and the completely free electron cases (more appropriate to alkali metals), as described below. As far as transport is concerned, one can use the Stoner two-band model, which is a two-fluid model (as used for electrons and holes in semiconductors) with one population of electrons with spin up and another with spin down, along with the corresponding spin-polarized densities of states (Fig. 4.14, Fig. 4.15 and Himpfel et al. [4.10].)

In ordinary crystalline nonmagnetic materials, the electronic band structure is built from the lattice (periodic) potential seen by a single electron (with any spin state) in the structure. Mathematically, this amounts to solving the Schrödinger equation corresponding to that potential and calculating its eigenfunctions (spin-independent wavefunctions). The eigenvalues are the ordinary bands. In a magnetic material, one must include exchange effects (which derive from Pauli exclusion principle-dependent electrostatic interactions that yield non-local interactions), and one must account explicitly for spin in the wavefunctions. Several methods exist to do this, such as the LSDA (local spin density approximation, see Fig. 4.1) which is a spin extension of the LDA (local density approximation) where one builds a local approximation to the exchange interaction from the local density of electrons [4.39]. The local spin density approximation (see Fig. 4.1) formalism provides a reliable description of the magnetic properties of transition metal systems at low temperatures. It also provides a mechanism for generating non-integer effective numbers n_B of Bohr magnetons, together with a plausible account of the many-electron nature of magnetic moment forma-

tion at $T = 0$ K. The bands obtained depend on spin, as depicted in the figures cited earlier. One can obtain the spin-dependent band structure from the spin-polarized density of states for each spin polarization (up \uparrow or down \downarrow , also called the majority and minority, like in ordinary semiconductors). Tables 4.7 and 4.8 give the polarizations and some spin-dependent band-structure quantities for representative transition metals and their alloys.

This semiconductor-like nomenclature (majority–minority) will eventually become confusing when we start dealing with metals and semiconductors simultaneously. For the time being, however, this nomenclature is acceptable so long as we are dealing solely with magnetic metals, and one can define a new type of gap (originating from the exchange interaction) called the exchange splitting or (spin) gap between two spin-dependent bands (Fig. 4.14 and Fig. 4.15). This explains the existence of novel materials such as half-metals, which can be contrasted with semi-metals (graphite) where we have a negative electronic gap because of valence and conduction band overlap.

Half-metals (such as CrO_2 and NiMnSb) possess one full spin-polarized band (up for instance) while the other (down) is empty. These materials are very important for spintronics and (especially) when injecting spin-polarized carriers.

4.2.4 Prospects for Spintronics and Quantum Information Devices

Presently, we are witnessing the extension of electronics to deal with spin and charge instead of charge only, the realm of traditional electronics. The reason spin becomes interesting and useful stems from the following ideas. As device integration increases and feature length decreases towards the nanometer scale, the spins of individual carriers (electrons or holes) become good quantum numbers. This means that spin value is conserved over the nanoscale (the spin diffu-

sion length is typically 5–50 nm), whereas it was not previously (in the micron regime), so it can be used in the nanometer regime to carry useful information. This means that carriers transport energy, momentum, charge and additionally spin. In addition, there is the potential that quantum computers could be constructed from spintronic components [4.25]. In perfect analogy with ordinary electronics, spintronics is based on four pillars:

1. Spin injection: How do we create a non-equilibrium density of spin-polarized carriers – electrons with spin up n_\uparrow (or down n_\downarrow) or holes with spin up p_\uparrow (or down p_\downarrow)? This can be viewed as the spin extension of the Haynes–Shockley experiment, and it can be done optically or electrically using thin magnetic layers serving as spin filters or analyzers/polarizers as in spin valves (Table 4.1). Spin injection can also be achieved with carbon nanotubes since they do not alter the spin state over large distances (Chapt. 51).
2. Spin detection: How do we detect the spin and charge of a non-equilibrium density of spin-polarized carriers?
3. Spin manipulation: How do we alter and control the spin and charge states of a non-equilibrium density of spin-polarized carriers?
4. Spin coherence: How do we maintain the spin and charge states of a non-equilibrium density of spin-polarized carriers over a given propagation length?

Spintronics is based, like microelectronics, on particular materials, their growth techniques (epitaxial or other) and their physical properties (electrical, mechanical, magnetic, thermal), as well as the ability to fabricate thin films and objects of reduced dimensionality (quantum dots, quantum wires, quantum pillars, clusters) and a knowledge of different processing steps (oxidation, diffusion, doping, implantation, etching, passivation, thermal insulation, annealing, texturing, sputtering, patterning) that can be used to build useful devices. All of the techniques established in the

Table 4.7 Spin polarization expressed in % for several ferromagnetic materials according to several authors. The discrepancies between the different results stem from the various approaches used to estimate the density of states at the Fermi level, and points to how difficult it is to obtain a unanimous figure. Note that for a half-metal like CrO_2 or NiMnSb , the polarization is 100%

field of microelectronics must be enlarged and extended to magnetism-based electronics (magnetoelectronics), which highlights the challenge of controlling magnetic interactions that have an anisotropic vectorial character in contrast to the scalar electrical interactions (based solely on charge) present in conventional microelectronic devices. Magnetoelectronics introduces the notions of anisotropy (magnitude, nature and direction), coercivity, saturation magnetization, and so on, which need to be controlled during growth (magnetic field-assisted growth or epitaxial growth must further developed in order to favor magnetic anisotropy along desired directions). For instance, there is, in some devices, the need to grow amorphous metallic magnetic layers (in order to get a very small anisotropy, resulting in a very magnetically soft layer), and these may be harder to grow than amorphous semiconductors or insulators (in metals, a cooling speed of one million degrees per second is typically needed to get an amorphous material). Temperature is a very important

parameter, since ferromagnetism (antiferromagnetism) is lost above the Curie (Néel) temperature. New types of materials emerge when spin-polarized carriers are used: for instance, half-metallic materials (such as CrO₂ and NiMnSb) that possess carriers that are completely polarized in terms of spin (all up or all down). Additionally, magnetic interactions can be based on localized, free, itinerant, para-, dia-, ferro-, antiferro- or ferrimagnetic materials, which can be electrically metallic, insulating or semiconducting. For instance, the possibility of controlling ferromagnetic interactions between localized spins in a material using transport carriers (electrons or holes), as well as the demonstration of efficient spin injection into a normal semiconductor, have both recently renewed the interest in diluted magnetic semiconductors. If made functional at a reasonably high temperature, ferromagnetic semiconductors would allow one to incorporate spintronics into usual electronics, which would pave the way to integrated quantum computers (Table 4.1).

5. Defects in Monocrystalline Silicon

The aggregation of intrinsic point defects (vacancies and Si interstitials) in monocrystalline silicon has a major impact on the functioning of electronic devices. While agglomeration of vacancies results in the formation of tiny holes (so-called “voids”, around 100 nm in size, which have almost no stress field), the aggregation of Si interstitials exerts considerable stress on the Si matrix, which, beyond a critical size, generates a network of dislocation loops around the original defect. These dislocation loops are typically microns in size. Consequently, they are much more harmful to device functioning than vacancy clusters. However, the feature size in electronic devices has now shrunk down to the 100 nm scale, meaning that vacancy aggregates are also no longer acceptable to many device manufacturers.

This chapter is intended to give an introduction to the properties of intrinsic point defects in silicon and the nucleation and growth of their aggregates. Knowledge in this field has grown immensely over the last decade. It is now possible

to accurately simulate the aggregation process so that the defect behavior of semiconductor silicon can be precisely tailored to the needs of the device manufacturer. Additionally, the impact of various impurities on the aggregation process is elucidated.

As the feature size continues to shrink in device industry, a thorough understanding of defect behavior in bulk silicon becomes more and more important. Three major defect types relevant to device performance have been identified: vacancy aggregates (known as “voids”, which usually have a size of less than 150 nm); Si interstitial clusters embedded in a network of dislocation loops, each of which extend over several microns (L-pits); and large grown-in oxygen precipitates. The latter generate stacking faults (OSF) during wafer oxidation. The voids form in the center of the crystal, while L-pits are observed in the outer region. The two concentric defect regions are usually separated by a small OSF ring. The type of defect that develops in the growing crystal is determined by a simple parameter: the ratio of

the pull rate to the temperature gradient at the growth interface. In industry, crystals with only one type of defect – voids – are produced almost exclusively. The formation and behavior of voids has been studied intensively and is accurately described by current theoretical models. As the feature size is now approaching the void size, the growth of so-called “perfect silicon” with almost no detectable defects may be adopted. Furthermore, the doping of crystals with impurities like nitrogen or carbon is being widely investigated. These impurities can significantly reduce the defect size, but they may also have harmful effects, such as enhancing the generation of OSFs. Some models have recently been proposed which may allow us to predict some of the effects of impurities.

5.1 Technological Impact of Intrinsic Point Defects Aggregates

Single intrinsic point defects in silicon – vacancies and interstitials – have not been found to have any negative impact on device performance so far. However, if they aggregate into clusters they can be even detrimental to device functionality. This is also true of extended defects like dislocations. When silicon wafer technology was in its formative years, much of the work devoted to improve wafer quality focused on controlling dislocation density in the silicon crystals, as it was not possible to grow dislocation-free crystals. However, with the introduction of dislocation-free crystal growth processes into mass production, the issue of extended dislocations in relation to bulk silicon quality vanished. As the feature size decreased and the demand for higher device performance increased, it soon became apparent that intrinsic point defects and their aggregation during the cool-down phase of the crystal growth process were having an increasingly negative impact on device performance and yield. Historically, one of the first serious challenges in this regard was the aggregation of Si interstitials in floating zone (FZ)-grown crystals, which results in a local network of dislocation loops (secondary defects), so-called “A-swirls” [5.1] or L-pits [5.2]. Although the diameters of these dislocation loops are only a few microns, they are large enough to generate hot spots in the space charge regions of high-power devices [5.3, 4]. In the second half of the 1980s, the industry began to encounter problems with the early breakdown of the gate oxide in memory devices based on Czochralski (CZ)-grown silicon [5.5]. After intensive gate oxide integrity (GOI) investigations, it was found that the root cause of the gate oxide degradation was tiny micro holes – voids – which were formed by vacancy aggregation during crystal growth [5.6, 7]. Each void is thermally stabilized by an oxide layer present on its inner surface. After wafer polishing, the voids show up as dimples or laser light scattering (LLS) defects on the wafer surface, causing a local thinning of the gate oxide [5.8, 9]. Voids are considerably smaller (less than 150 nm) than A-swirl defects, and so their impact on device performance is only apparent if the location of a void coincides with that of an active element, such as a transistor. In addition, most of these defective transistors can be repaired due to the built-in redundancy of memory chips. Consequently, vacancy aggregates are tolerable for many devices, so long as their density is insignificant compared to those of device process-induced defects. This should be contrasted with A-swirls or L-pits, which al-

ways result in permanent device damage due to their large sizes.

Empirically, it has been found that gate oxides 40–50 nm thick are most susceptible to void defects [5.9]. Thinner oxides show higher GOI yields, and when the thickness drops below 5 nm the influence of voids on the GOI yield disappears [5.10, 11]. However, as the feature size continues to shrink, additional adverse effects have been identified, such as shorts between trench capacitors and lack of device reliability [5.12, 13]. As the design rule becomes equal to or less than the void size, these problems are expected to aggravate and device manufacturers may have to switch to materials with extremely small defect sizes or those that contain virtually no defects.

There are three main ways to achieve silicon with no harmful intrinsic point defect aggregates. The first is to grow silicon crystals in a regime where Si interstitials and vacancies are incorporated in equal concentrations (see Sect. 5.3.2), resulting in almost complete mutual annihilation of point defects (so-called “perfect” or “pure” silicon) [5.14–17]. The method inevitably involves lower pull rates and very tight control over crystal growth parameters, which yields considerably lower throughput and higher costs, in particular for 300 mm crystal growth.

The second approach is the growth of nitrogen-doped crystals with very fast pull rates (high cooling rates) and subsequent high-temperature ($\approx 1200^\circ\text{C}$) wafer annealing [5.18]. Nitrogen doping in conjunction with a fast pull rate decreases the vacancy aggregate size (Sect. 5.3.3 and Sect. 5.3.4) [5.19, 20], meaning that they are easy to dissolve using a high-temperature wafer treatment. Void annihilation first requires the dissolution of the inner oxide layer, which in turn, necessitates the outdiffusion of oxygen. Thus, annealed wafers only exhibit a near-surface defect-free region $\approx 10\mu\text{m}$ in depth, which is, however, sufficient for device manufacturing. Annealed wafers also take advantage of the notable mechanical strengthening effects of nitrogen doping [5.21–23], which helps to suppress slippage generation during high-temperature treatment. One very recent development is rapid thermal wafer annealing at a temperature of around 1300°C . At this temperature, outdiffusion of oxygen is not necessary because the oxygen concentration is usually below that required for oxygen solubility, so the inner oxide layer dissolves throughout the bulk and the voids collapse. This process yields silicon of a simi-

lar quality to that resulting from perfect silicon crystal growth.

The third method is the well-known epi wafer approach.

All of these methods require rather precise defect engineering in order to obtain the properties demanded by the device industry, except in the case of pp+ epi wafers.

Here, the high boron concentration of the substrate suppresses intrinsic point defect aggregation (Sect. 5.3.4) and enhances oxygen precipitation in the bulk. Therefore, this wafer type not only provides a defect-free epi layer, but also gives metallic contaminants superior internal gettering (impurity removal) abilities and high slip resistances.

5.2 Thermophysical Properties of Intrinsic Point Defects

Understanding intrinsic point defect aggregation undoubtedly requires rather exact knowledge of their respective thermophysical properties.

The intrinsic point defects – vacancies and Si interstitials – can exist in different configurations. Generally, six localized point defect configurations of high symmetry are considered: the vacancy and the split-vacancy on the one hand, and the tetrahedral, the hexagonal, the bond-centered and the [100] split or dumbbell Si interstitial on the other [5.24]. While the localized configuration works rather well for vacancies, theoretical calculations strongly favor an extended configuration of lower symmetry for Si interstitials [5.25, 26]. The extended self-interstitial model was originally proposed to explain the high pre-exponential factor in the coefficient of self-diffusion, and this model now has support from theoretical calculations [5.24, 27, 28]. According to theory, the high value of the pre-exponential factor results from the multitude of self-interstitial configurations with similar energies and the significant lattice relaxations that accompany some of these configurations.

Vacancies and Si interstitials can also exist in various charged states (such as V^{2+} , V^+ , V^0 , V^- , V^{2-}), and at the high temperatures ($> 1000^\circ\text{C}$) where point defects start to aggregate all states should be present in dynamic equilibrium [5.29]. Due to this equilibration, it is not meaningful to assign a specific charge to vacancies and Si-interstitials, respectively. However, atomistic calculations show that the charged states are much higher in energy and so their populations should be negligible. So far, there is no indication that charged states have any impact on defect aggregation and so they are not considered in current defect nucleation models.

Unfortunately, it is generally not possible to observe intrinsic point defects directly and so their thermophysical properties cannot be measured directly either. Thus, indirect approaches must be used that involve fitting defect concentrations along with many other parameters. Various experimental systems have been used to

infer the thermophysical properties of point defects. The most common of these are metal diffusion experiments where a metallic contaminant such as zinc, gold or platinum is introduced into the bulk via high-temperature drive-in diffusion [5.30–32]. The diffusion rate of the metallic impurity, which is easily detectable using standard methods, is related to the mobility and the concentration of intrinsic point defects (kick-out and Frank–Turnbull mechanism), which provides a way to indirectly probe the behavior of the point defects. These experiments yield good estimates for the product $C_{\text{eq}}D$ of the equilibrium concentration C_{eq} and the diffusivity D for self-interstitials I and vacancies V, respectively. The following values are derived from zinc diffusion results [5.33]:

$$C_{\text{I}}^{\text{eq}} D_{\text{I}} = 1.5 \times 10^{26} \exp(-4.95 \text{ eV}/k_{\text{B}}T) \text{ cm}^{-1} \text{ s}^{-1}$$

and

$$C_{\text{V}}^{\text{eq}} D_{\text{V}} = 1.3 \times 10^{23} \exp(-4.24 \text{ eV}/k_{\text{B}}T) \text{ cm}^{-1} \text{ s}^{-1}.$$

Another frequently used experimental method is the defect analysis of CZ crystals grown with varying pull rates. In this case, the observables are the dynamic responses of the oxidation-induced stacking fault (OSF) ring and the interstitial–vacancy boundary as a function of changes in crystal growth process conditions [5.2, 34–36] (Sect. 5.4). These observables have been quantitatively correlated to intrinsic point defect distributions in crystals and, can therefore be used to derive thermophysical properties [5.37]. Of particular importance is the complementary nature of crystal growth and metal diffusion experiments with regard to parametric sensitivity. The high temperature dependence of the IV–boundary and its sensitivity to self-interstitial and vacancy competition implies that these experiments are suitable for determining some pre-exponential coefficients. The metal diffusion experiments, which can be carried out over a wide range of temperatures, are particularly useful for probing activation energies.

Fig. 5.1 Diffusivities and equilibrium concentrations of vacancies and Si interstitials, respectively. (After [5.41])

In recent years, RTA experiments with fast cooling rates have been carried out with silicon wafers to investigate the influence of the free vacancy concentration on oxygen precipitation [5.17, 38]. By heating the wafers to above 1150 °C, detectable concentrations of Frenkel pairs are created in the wafer bulk. The wafer is then held at this temperature for around 10 s to allow the self-interstitials to diffuse out, resulting in a near-equilibration of both interstitials [$C_I^{\text{eq}}(T)$] and vacancies [$C_V^{\text{eq}}(T)$]. Following this rapid equilibration, the wafer is rapidly cooled (at rates of ≈ 100 °C/s) to freeze in the vacancy excess which can subsequently be probed via its impact on oxygen precipitation. This technique is especially useful for gaining information on [$C_V^{\text{eq}}(T) - C_I^{\text{eq}}(T)$] at various temperatures [5.39]. Quenching experiments at different holding tempera-

tures are also reported for hydrogen-doped samples, which allow us to quantitatively measure the VH_4 complex [5.40]. From these results, the vacancy formation energy was deduced as ≈ 4 eV with relatively good accuracy.

Experimental data that relate to the recombination coefficient of vacancies and Si interstitials are scarce [5.42, 43]. Nevertheless, there is general agreement that recombination between vacancies and Si interstitials is so fast that the product of the concentrations of both species is always in thermal equilibrium. The exact value is therefore not relevant to subsequent discussion here.

There have been numerous attempts to compute the thermophysical properties of point defects directly by atomistic simulations. The most important aspect of these atomistic calculations is the accuracy of the assumed interatomic interaction. As the ab initio approach which explicitly considers electronic interactions is extremely computationally expensive and therefore limited to small systems and zero temperature, most simulations are carried out using empirical potentials, such as the Stillinger–Weber or Tersoff potential functions, discarding explicit representations of electronic interactions. An excellent overview of the current status of this field is given by Sinno [5.44]. A parameter set that yields rather good results for defect aggregation is shown in Fig. 5.1. It is clear that the difference between the vacancy and Si interstitial concentrations at the melting point is only around 30% in favor of vacancies. On the other hand, vacancies diffuse more slowly than Si interstitials. These two properties are of great relevance to the peculiar defect behavior of silicon.

In the past, fitted values for equilibrium concentrations and diffusivities inferred from various experimental data often spread over many orders of magnitude, meaning that they were of little help. However, in recent years, theoretical methods and the accuracy of experimental data have significantly improved and the predicted values are now in much better agreement with those gleaned from experiments. Today, the uncertainties in thermophysical data are usually less than 10%.

5.3 Aggregates of Intrinsic Point Defects

5.3.1 Experimental Observations

As pointed out in Sect. 5.1, the dominant intrinsic point defect aggregates in silicon single crystals are voids

and L-pits/A-swirls. Figure 5.2 shows a TEM image of a void with a 5 nm oxide layer on the inner surface. Oxidation of the inner surface is not observed in FZ crystals due to their very low oxygen contents. The

Fig. 5.2 TEM picture of a void/COP (left). The inner surface of the void is covered by an oxide layer (right). (After [5.52])

Fig. 5.3 TEM picture of an L-pit. (After [5.53])

thickness of the oxide layer decreases with increasing cooling rate of the growing crystal. A strain field is generally not observed around the void. Usually, voids exhibit octahedral morphologies, but they can change to platelet or even rodlike shapes if the crystal is doped with nitrogen (Sect. 5.3.4). Under standard growth conditions, twin voids consisting of two partial octahedral voids are predominantly observed [5.45, 46]. At lower oxygen contents and higher cooling rates of the growing crystals, single octahedral voids are preferentially formed [5.47, 48]. Typical sizes range from 70–200 nm depending on the crystal growth conditions. Historically, different notations were introduced for this type of defect

depending on their delineation or the detection technique used: crystal originated particle (COP) [5.49], laser light scattering tomography defect (LSTD) [5.2], flow pattern defect (FPD) [5.50], and D-defects [5.51]. Today, it is generally accepted that they all denote the same defect type: vacancy aggregates.

The TEM image of an L-pit is depicted in Fig. 5.3. The network of perfect dislocation loops characteristic of this defect type is clearly visible. The core of the defect is a self-interstitial aggregate which forms an extrinsic stacking fault [5.53, 54]. When the stacking fault reaches a critical size, the strain exerted on the crystal lattice is relaxed by the generation of dislocation loops. It is believed that the B-swirl observed in FZ

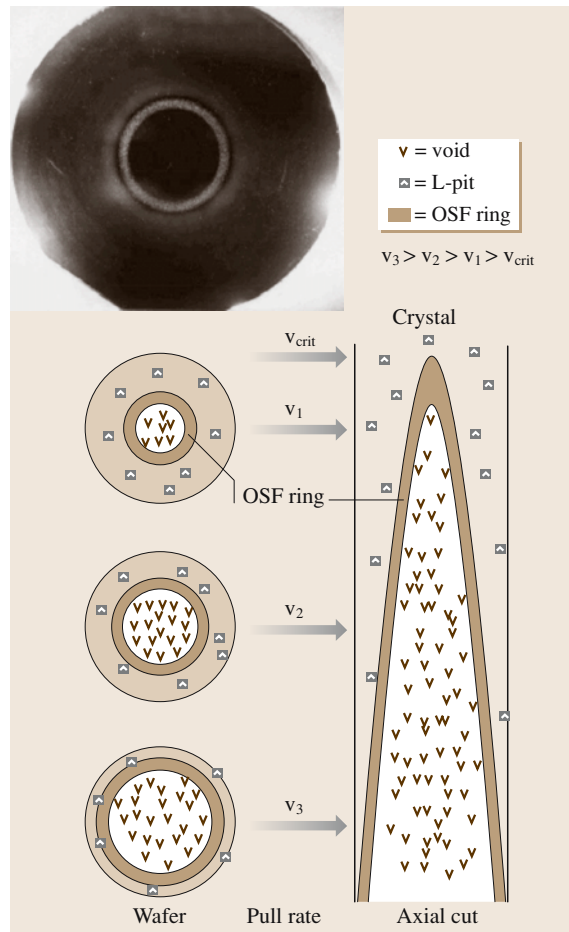

Fig. 5.4 Variation in the radial defect behavior of a CZ crystal as a function of pull rate. The insert on the left shows a wafer from the crystal part grown with medium pull rate. The defects were delineated by Secco etching

crystals [5.55,56] is most likely related to self-interstitial aggregates with sizes below the critical limit [5.57,58]. While the B-swirl can be annihilated by appropriate high-temperature treatment, the L-pit/A-swirl is extremely stable.

In the case of epi wafers, voids at the substrate surface are covered by the epilayer and no defects are generated in the epilayer. However, if the layer thickness is very thin ($< 1 \mu\text{m}$), a dimple remains at the epilayer surface which is detectable by laser light scattering [5.60]. In contrast to voids, L-pits always generate clearly visible and harmful defects in the epilayer [5.61] and are therefore unacceptable to device manufacturers. It is well-established that the pull rate V and the axial temperature gradient G at the growth interface of the growing crystal have the biggest influence on the defect types that develop in the growing crystal [5.34,35,62] and their spatial [5.36] as well as their density/size distributions [5.59]. At high pull rates, vacancy-related defects (voids) are observed over the entire crystal volume (Fig. 5.4). When the pull rate is reduced, oxidation-induced stacking faults (OSFs) develop in a small ring-like region near the crystal rim [5.63]. If the pull rate is decreased further, the ring diameter shrinks and L-pits are detected in the area outside the OSF ring [5.2]. No voids are found in this outer region. Thus, the OSF ring obviously represents the spatial boundary between vacancy- and self-interstitial-type defects. At a critical pull rate, the void region and the OSF ring disappear completely and only L-pits are detected. In FZ crystals with their inherently low oxygen contents, no OSF ring is observed as a boundary; instead a defect free-zone is observed as the boundary [5.64].

The radial position of the OSF ring can be approximately described by the equation [5.36]:

$$V/G(r) = \xi_{\text{tr}} = 1.34 \times 10^{-3} \text{ cm}^2 \text{K}^{-1} \text{min}^{-1},$$

Here r is the radial position. Thus, the parameter V/G controls the type of grown-in defect: if $V/G > \xi_{\text{tr}}$ vacancy aggregates develop, while for $V/G < \xi_{\text{tr}}$ Si interstitial-related defects are observed. This was first recognized by Voronkov in 1982 [5.62].

A further important parameter for the control of grown-in defects is the thermal history of the crystal. While its influence on the type of defect that develops in the growing crystal is negligible, detailed investigations have revealed a strong effect of cooling rate on the defect density/size distribution. For a crystal cooling in the temperature range between roughly 1000°C and 1100°C , there seems to be an exponential relation between the void density N_{void} and the dwell time t

Fig. 5.5 Void density as derived from GOI measurements as a function of the dwell time of the growing crystal at $\approx 1100^\circ\text{C}$. The straight line denotes simulation results. The various data points relate to different growth processes. (After [5.59])

(Fig. 5.5) [5.65]. The defect density data in Fig. 5.5 were derived from GOI measurements that can detect much smaller defect sizes than delineation techniques based on etching and/or laser light scattering. The correlation between the various detection methods down to LSE sizes of $0.12 \mu\text{m}$ was found to be rather good [5.19].

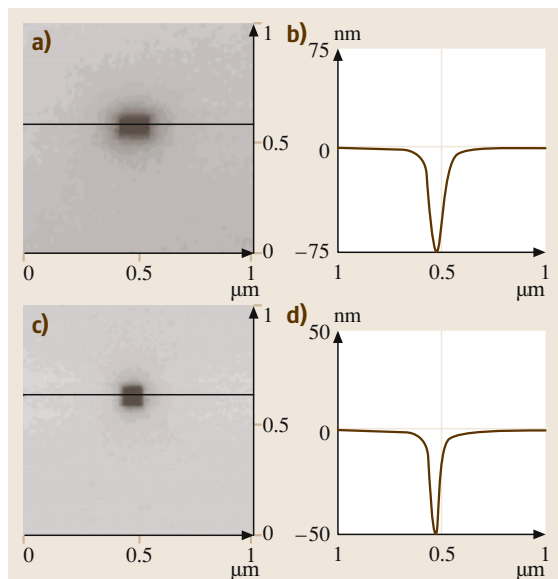

Fig. 5.6 Atomic force microscopy measurements of voids at the wafer surface. The depth of the surface void is rather close to its original size in the crystal. Samples are from a slowly cooled (left) and a rapidly cooled crystal (right). (After [5.60])

The exact upper value of the above temperature range depends on the crystal growth conditions and will be shown (Sect. 5.3.3) to coincide with the void nucleation temperature. The width of the selected temperature interval, on the other hand, does not have much impact on the above empirical relation. As will be discussed below, the relevant temperature interval is rather small [5.66]. Hence, the dwell time might just as well be replaced by the inverse of the cooling rate at the nucleation temperature.

It was further observed that the average void size increases as dwell time increases (with slower cool-

ing rates) and vice versa (Fig. 5.6) [5.59, 67]. Another striking feature is the characteristic change in the defect density/size distribution across the crystal diameter (Fig. 5.7) [5.68]. While large voids of low density prevail in the crystal center, the distribution gradually shifts to small sizes and high density towards the boundary of the void region. As the cooling rates of the crystal center and rim are almost the same, this remarkable variation in the density/size distribution must be related to the radial inhomogeneity of $V/G(r)$. Unfortunately, similar data are not yet available for L-pits. The behavior of this defect type is more complex, as small interstitial aggregates which do not generate dislocation loops are not detected as L-pits.

Valuable information about the defect nucleation temperature is obtained from transient growth experiments where the pull rate is reduced to zero and the growth process is halted when a certain crystal length has been reached [5.69–71]. After a certain amount of time has elapsed, growth is resumed and the crystal is grown to full length. During the halting period, the various crystal positions are at different temperatures according to the axial temperature gradient of the crystal. By analyzing the axial defect behavior of the as-grown crystal, one can identify the temperature ranges where specific defect types nucleate and grow in size. The results of those experiments clearly demonstrated that the nucleation temperature of voids lies between 1000°C and 1100°C and varies with the growth conditions. It was also demonstrated that the nucleation and growth period of the voids occurs over a temperature interval of less than 50 K [5.72]. Void growth is then obviously stopped by the formation of the inner oxide layer. The oxide layer continues to grow down to relatively low temperatures. The scarce data available for L-pits indicate a similar temperature range for nucleation [5.73].

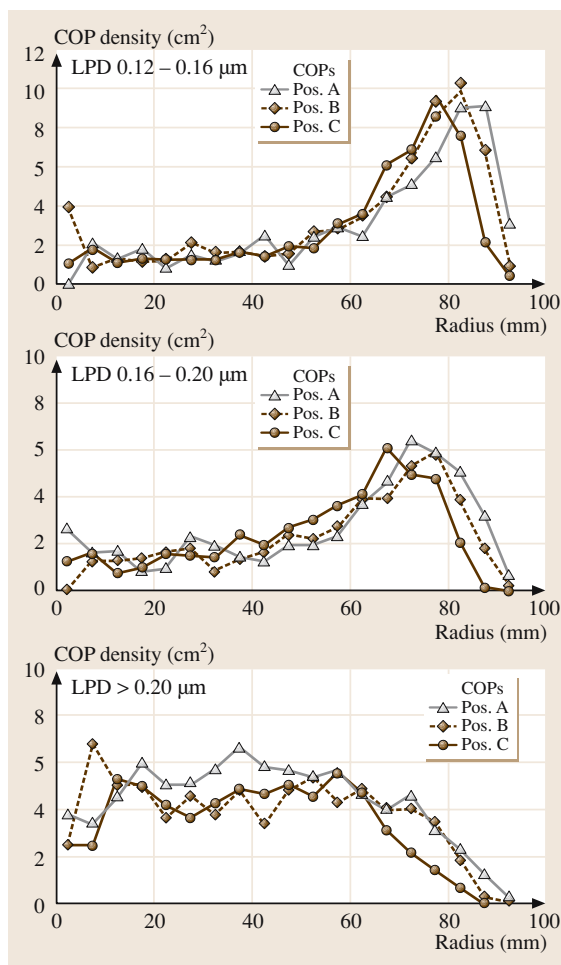

Fig. 5.7 Radial variation in the density/size distribution of voids/COPs across a wafer as measured by laser light scattering. The light point defect size (LPD) correlates well to the actual void size. The positions A, B and C relate to different axial crystal positions

5.3.2 Theoretical Model: Incorporation of Intrinsic Point Defects

The incorporation of intrinsic point defects is the result of two competing fluxes at the growth interface: a vacancy and an interstitial flux which are both directed into the crystal (Fig. 5.8). Each of the two fluxes consists of two components. The first flux component is driven by the advancing growth interface, which generates a convective flux proportional to the pull rate V , and the second is driven by the vacancy/interstitial recombination behind the interface, which creates a concentration gradient and, in turn, a Fickian diffusion flux. The latter is proportional to G . If the pull rate is low,

Fig. 5.8 Schematic picture of the incorporation of vacancies (V) and Si interstitials (I), respectively, into the growing crystal. The insert on the right shows the radial variation of the remaining species after V-I recombination has ceased and supersaturation starts

then the Fickian diffusion dominates over the convective flux. As self-interstitials diffuse significantly faster than vacancies, the self-interstitial flux wins over the vacancy flux. During crystal cooling, V-I recombination virtually eliminates the vacancies and the surviving self-interstitials are driven into supersaturation and finally aggregate. On the other hand, at fast pull rates the convective flux dominates and, due to the larger equilibrium concentration of vacancies compared to that of

Fig. 5.9 Schematic radial variation in defect types as a function of the radial variation of V/G

Fig. 5.10 Radial variation in the crossover between the transition value ξ_{tr} and $V/G(r)$ as function of decreasing pull rate V

self-interstitials, more vacancies flow into the crystal, resulting in vacancy aggregates. A similar change in the prevailing defect type is obtained when G is varied. The above model, originally proposed by Voronkov [5.62], yields the previously mentioned parameter V/G which determines the defect type.

In standard growth processes, G always exhibits a notable increase from the center towards the crystal rim, which (at sufficiently low pull rates) results in a vacancy excess in the center, while Si interstitials dominate at the crystal rim, as indicated in Fig. 5.9. Figure 5.10 illustrates how the radial position of the crossover between ξ_{tr} and $V/G(r)$ and hence the boundary between the void and L-pit regions is shifted when V is varied.

The exact value of ξ_{tr} is still under discussion, because G has to be taken directly at the interface where the thermal field in the crystal changes very rapidly [5.36, 74]. Therefore, as yet it has not been possible to accurately measure G at the growth interface [5.75]. Fortunately, computer simulations with sufficiently refined meshes permit a rather accurate calculation of G . Based on these calculations, a value of $0.13 \text{ mm}^2 \text{ min}^{-1} \text{ K}^{-1}$ has been determined from growth experiments, with hot zones of different G s [5.34], which is widely accepted for now.

It should be noted that the above behavior is probably unique to silicon as it stems from the peculiar phenomenon that the vacancy and Si interstitial equilibrium concentrations in crystalline silicon are very similar, but C_v^{eq} is slightly higher than C_I^{eq} , although the diffusivity of Si interstitials exceeds that of vacancies at the melting point. In addition, the quantitative relationship between

the relevant parameters which allows the changeover in defect behavior to occur in accessible growth rate regimes is quite astonishing. The time-dependent behaviors of the point defect concentrations are determined by the species conservation equations [5.76]

$$\begin{aligned} \frac{DC_I}{Dt} = & \nabla \left[D_I(T) \nabla C_I - \frac{D_I(T) C_I Q_I^*}{k_b T^2} \nabla T \right] \\ & - k_{IV} (C_I C_V - C_I^{\text{eq}} C_V^{\text{eq}}) \\ & - \frac{\partial}{\partial t} \int_2^\infty n f_1(n, r) dn, \end{aligned} \quad (5.1)$$

where Q_I^* is the reduced heat of transport for Si interstitials, which describes the rate of material flow due to a temperature gradient. A similar expression applies for vacancies (just exchange the I and V notations). The substantial derivative $D/Dt = [\partial/\partial t + V(\partial/\partial z)]$ is defined here as the rate of change of species concentration at a point moving with the velocity (V) of the advancing growth interface. This term relates to the incorporation of species due to convection. The first term on the left-hand side accounts for Fickian diffusion and the second for thermodiffusion. The last term represents the loss of point defects into their aggregates of all possible sizes. This term can be neglected as long as the supersaturation of the surviving species has not increased to the point where cluster nucleation starts. A detailed analysis also reveals that thermodiffusion has no detectable impact. Hence, the simple picture drawn above – which only takes into account convection and Fickian diffusion – is quite reasonable. Based on these simplifications, the incorporated vacancy concentration can be calculated from a simple expression [5.74, 77].

$$C_V(r) \approx [C_V^{\text{eq}}(T_m) - C_I^{\text{eq}}(T_m)] \left(1 - \frac{\xi_{tr} G(r)}{V} \right). \quad (5.2)$$

This expression is also applicable to Si interstitials (at $V/G < \xi_{tr}$). It then defines the incorporated Si interstitial concentration C_I with a minus sign.

If V/G approaches ξ_{tr} , then the vacancy and Si interstitial fluxes become equal and both species are annihilated by V–I recombination. Thus, the incorporated V and I concentrations are negligible and no aggregates can form. This particular condition must be met for the growth of so-called perfect silicon.

5.3.3 Theoretical Model: Aggregation of Intrinsic Point Defects

Due to the technological dominance of vacancy-rich silicon, previous theoretical investigations of defect aggregation have mainly focused on the formation of voids. In addition, it was also easier to verify the theoretical results for vacancy aggregation because voids are not obscured by the secondary defect generation that occurs for L-pits.

From Fig. 5.11, it can be seen that, for a standard growth process, the V-supersaturation already begins to build up at around 1200 °C [5.78], which is well above the experimentally determined nucleation temperature of voids (≈ 1100 °C). Thus, the supersaturation C_V/C_V^{eq} necessary to nucleate voids is appreciable, ≈ 10 [5.76], as estimated from Fig. 5.11. This fact also allows us to decouple the phase where V–I recombination is the major vacancy loss mechanism from the phase where nucleation dominates the vacancy loss, so that one can assume that the cluster formation starts with a fixed concentration which can be calculated from (5.2). For special growth processes that are designed to minimize or even eliminate voids, the starting vacancy concentration after V–I recombination is so small that the beginning of supersaturation (and hence void nucleation) occurs at notably lower temperatures [5.77].

The first vacancy aggregation calculations were performed with a model that was originally developed to simulate oxygen precipitation [5.59, 79]. For the formation of small clusters (less than 20 vacancies), the kinetics are described by chemical rate equations; for

Fig. 5.11 Simulated variation in the vacancy concentration in growing crystals as a function of temperature for rapidly and slowly cooling growth processes. The density of voids nucleated at around 1100 °C and below is shown on the right scale

larger clusters, the rate equations are expanded into a continuum formulation that yields a single Fokker–Planck equation. The void shape is assumed to be spherical. Input data are the computed temperature field, which can be quite accurately calculated using commercially available standard codes, and the surviving vacancy concentration after V–I recombination has ceased. Besides the physical properties of the vacancies and Si interstitials, the surface energy must also be known, which is estimated to be around 950 erg/cm^2 .

As can be seen from Fig. 5.11, the computer simulations yield a nucleation temperature of around 1100°C , which agrees fairly well with the experimental results. The prediction of the correct aggregation temperature has been a matter of discussion. With the above input data, one ends up with a far lower aggregation temperature than those observed [5.80, 81]. The main reason for this is that the nucleation process does not start as a small octahedral void as previously assumed, but rather as an “amorphous cloud” of vacancies which, after some time, relaxes into an octahedron with (111) facets [5.82]. Proper modeling of this initial nucleation process with atomistic calculations does indeed shift the calculated aggregation temperature into the experimentally observed range.

The results in Fig. 5.11 also demonstrate that a higher cooling rate obviously decreases the nucleation temperature. The origin of this effect is the increased supersaturation, which builds up because there is less time for vacancy consumption. Due to the shift in the nucleation temperature, the residual vacancy concentra-

tion after void formation remains higher for fast cooling rates than for slow cooling. This has an important effect on the nucleation of oxygen precipitates, as the latter is strongly enhanced by a higher free vacancy concentration. Figure 5.12 illustrates the evolution of the void density/size distribution during the nucleation period. It is apparent that the maximum of the distribution is shifted to larger void sizes not only due to the growth of the previously nucleated voids, but also due to the fact that the newly nucleated clusters have a larger size. The latter effect results from the decreased supersaturation with higher void density, which, in turn, increases the critical radius for stable nuclei. Thus, only increasingly large clusters can nucleate towards the end of the nucleation period.

As depicted in Fig. 5.13, a fast cooling rate decreases the cluster size but increases their density and vice versa, which correlates well with the experimental data. The reason for this is the above-mentioned higher supersaturation at fast cooling rates, which entails a larger nucleation rate. The higher cluster density then effectively lowers the residual vacancy concentration. The clusters, however, have no time to grow and so remain small.

A similar effect is obtained when the initial vacancy concentration before the onset of nucleation is reduced [5.83]. A lower vacancy concentration causes a downward shift in the nucleation temperature, where the vacancy diffusivity is lower. As a consequence, they need more time to diffuse to sinks, which in turn drives up supersaturation and so more clusters of a smaller size are formed again. The behavior of the size distribution as a function of the initial vacancy concentration gives a simple explanation for the experimentally found radial variation in the void size distribution in Fig. 5.7. As

Fig. 5.12 Simulated evolution of the void density–size distribution at various temperatures of the growing crystal. The temperature difference between each curve is 4 K

Fig. 5.13 Simulated density/size distributions of voids for growth processes with different cooling rates

Fig. 5.14 Simulated radial variations in the vacancy and Si interstitial concentrations, respectively. (After [5.68])

Fig. 5.15 Simulated radial variation in the density/size distribution of voids and comparison with experimental data. (After [5.68])

the initial vacancy concentration decreases towards the crystal rim (Fig. 5.14), the average size of a void shrinks but void density grows. Thus, the density of small voids

is low in the center, but increases towards the crystal rim until the vacancy concentration drops below a critical value, where the average void size is below the detection limit. On the other hand, the number of large voids shrinks with decreasing vacancy concentration. Therefore, the density of large COPs is highest in the center. This behavior is also fairly well reproduced by simulation (Fig. 5.15).

A simple expression that predicts a void density proportional to $q^{3/2}C_V^{-1/2}$ (q = cooling rate, C_V = initial vacancy concentration before nucleation starts) has been derived by Voronkov et al. [5.66]. This formula is obviously in excellent agreement with the experimental results (Fig. 5.16). A deviation from the above expression was reported for detached crystals, where significantly higher cooling rates can be achieved (2–70 K/min) [5.84]. In the latter case, this discrepancy was tentatively explained by a suppression of voids in favor of enhanced formation of oxygen precipitates at high cooling rates (> 40 K/min) [5.85]; in other words, so-called “oxide particles” nucleate at around 1100 °C rather than voids.

The $C^{-1/2}$ dependence is more difficult to verify experimentally because a change in the initial vacancy concentration entails a change in the nucleation temperature and so temperature-dependent parameters like diffusivities and equilibrium concentrations must be adjusted. Most of the current aggregation models do not consider the oxidation of the inner void surface, which stops void growth before the vacancies are essentially depleted. This has less impact on the void size distribution but considerably affects the residual vacancy concentration and therefore oxygen precipitation (Sect. 5.4).

Fig. 5.16 Void density as derived from GOI measurements as a function of cooling rate of the growing crystal. The straight line relates to predictions of the $q^{3/2}$ law

The occurrence of double voids is still under discussion. One attempt to explain this phenomenon is based on a partial oxidation of the (111) facets during void growth, which allows the incorporation of further vacancies at the unoxidized residual facet surface [5.86].

5.3.4 Effect of Impurities on Intrinsic Point Defect Aggregation

Nitrogen

Nitrogen has long been known to simultaneously suppress interstitial- and vacancy-related defects – A-swirls and D-defects/voids, respectively [5.88] – in floating zone (FZ)-grown crystals. The nitrogen concentrations required are very low ($< 2 \times 10^{14}$ at/cm³) and were found to be in the same range as the surviving residual intrinsic point defect concentrations.

In the case of Czochralski (CZ)-grown silicon, nitrogen has been an undesirable dopant in the past, because it enhances the formation of oxidation-induced stacking faults (OSF) [5.89]. As the nitrogen concentration increases, the OSF ring widens [5.90] until it extends over the entire crystal diameter. In addition, due to the comparatively high oxygen concentration ($3\text{--}8 \times 10^{17}$ at/cm³), the desirable defect suppressing effects of nitrogen are largely offset by the interaction of nitrogen and oxygen [5.91]. However, nitrogen still has a notable effect on the defect size: the higher the nitrogen concentration, the lower the defect size [5.19, 92]. This effect has recently become important, because a small defect size is highly favorable for defect annealing [5.16]. It was further found that nitrogen not only

reduces the defect size but also systematically changes the void morphology from octahedron to platelet and, finally, to rods or even rod clusters with increasing concentration (Fig. 5.17) [5.87]. Nitrogen doping has gained additional interest as it also strongly enhances oxygen precipitation [5.93–95] which can be used to improve the efficiency of gettering of metallic contaminants in low thermal budget device processes [5.96, 97].

Unfortunately, quantitative data on the chemical and physical properties of nitrogen in silicon are rare. Experimentally, it was found that nitrogen exists as N–N dimers in as-grown silicon [5.98], which has a diffusivity three orders of magnitude higher than oxygen at 1100 °C [5.99]. These diffusion experiments indicate that the N–N dimer is stable up to at least 1270 °C [5.100], which is in line with first-principles calculations of the N–N dimer configuration [5.101–103]. In contrast with the nitrogen molecule, the N–N dimer in silicon does not have any direct bonds between the two neighboring nitrogen atoms. Experiments with nitrogen-implanted silicon samples heated to melt temperature by a laser pulse and subsequently quenched to room temperature proved that roughly 10% of the nitrogen can be frozen on substitutional sites as single nitrogen atoms [5.104, 105]. The fact that substitutional nitrogen is generally not observed in regularly cooled samples suggests that substitutional nitrogen is not stable in silicon at lower temperatures [5.106].

As the nitrogen concentration needed to suppress A-swirl and D-defects is in the same range as the intrinsic point defect concentration before aggregation, it was suggested that nitrogen directly interacts with vacancies (V) and Si interstitials (I) and thus prevents their aggregation [5.107, 108]. One model proposes that the storage of vacancies in impurity complexes would gradually shift the transition value ξ_{tr} of V/G to higher values which, in turn, would explain the shrinkage of the void region with increasing nitrogen content [5.109]. On the other hand, the model also seems to imply that the A-swirl region simultaneously expands toward the crystal center, which is in conflict with experimental results. In particular, the Li-drift experiments of Knowlton et al. [5.110] proved that, despite the suppression of detectable COPs, the extent of the vacancy-rich region does not change due to nitrogen doping. Other attempts are based on the reduction of vacancy diffusivity due to the vacancy–nitrogen interaction [5.111] or on increasing the reaction barrier to vacancy absorption at the void interface [5.112]. However, the fact that nitrogen doping has no impact on the inner oxide layer growth of the voids [5.87] does not support the notion that nitro-

Fig. 5.17 Variation in void morphology as a function of nitrogen concentration and cooling rate of the growing crystal. (After [5.87])

gen modifies the properties of the void interface. None of these proposals gives any explanation for influence of nitrogen on Si interstitial aggregation.

First-principles calculations by Sawada et al. and Kageshima et al. [5.101, 102] have shown that the N–N dimer can form stable N_2V and N_2V_2 complexes, the latter being more stable due to a larger enthalpy of formation. Based on these results, it has been proposed that the vacancy aggregation is suppressed by the reaction

whereas the formation of Si interstitial agglomerates is prevented by the reaction

Nitrogen is not likely to be incorporated as a N–N dimer into the crystal. This is concluded from the experimental fact that nitrogen does not evaporate from the silicon melt and so it must be strongly bound to silicon atoms, which is not possible for a nitrogen molecule. It was therefore proposed that single nitrogen atoms are incorporated on interstitial (N_i) as well as substitutional sites (N_s) at the growth interface [5.113]. Behind the growth interface, the highly mobile interstitial nitrogen atoms then quickly form N–N dimers via $N_i + N_i \leftrightarrow N_2$ and nitrogen-vacancy complexes via $N_i + N_s \leftrightarrow N_2V$ inside the crystal. A ratio of $[N_i]:[N_s]=7:1$, which corresponds to 12% of the nitrogen at substitutional sites, has been determined from FZ crystals grown with various nitrogen contents. This is in good agreement with the above-mentioned experimental findings for substitutional nitrogen. As vacancies and Si interstitials have very similar concentrations at the melting point, reactions (I) and (II) mainly act as an additional V–I recombination path during crystal cooling, with only marginal impact on the levels of N_2 and N_2V . However, when recombination is complete and the vacancies or the Si interstitials have been wiped out, reaction (I) or (II) prevents the aggregation of the surviving species. Using this model, it has been possible to determine the radial variations of vacancies and Si interstitials in FZ crystals before the onset of defect aggregation [5.113]. This was achieved by measuring the radial extension of the COP and A-swirl region as a function of the nitrogen concentration. The result is in excellent agreement with theoretical predictions (Fig. 5.18). Surprisingly, the experimental data could not be fitted by assuming that the formation of N_2V_2 complexes prevails, as predicted by theoretical calculations. It is not clear whether the reaction to N_2V_2 is hampered by a high-energy barrier.

While this model works well for FZ crystals, it does not explain why the effect of nitrogen on defect aggregation is strongly diminished in CZ crystals. It is clear that the well-known interaction between nitrogen and oxygen, which results in the formation of N_xO_y complexes [5.114], is probably the origin of the vanishing nitrogen effect. However, it is also known that, despite oxygen levels of $5\text{--}6 \times 10^{17} \text{ at/cm}^3$, ample unreacted nitrogen is left in oxygen- and nitrogen-doped crystals to suppress defect aggregation [5.115]. As the experimentally confirmed N_2O complex is only stable up to about 700°C [5.114, 116], it has been proposed [5.113] that nitrogen reacts with oxygen at high temperatures according to

The existence of the NO complex has been theoretically predicted by Gali et al. [5.117]. It has a similar structure to the N_2 complex but with a smaller binding energy. The NO formation can occur directly close to the growth interface via $N_i + O_i \leftrightarrow NO$ or $N_s + O_i \leftrightarrow NO + V$. The latter reaction obviously generates additional vacancies, which should, however, only have a small impact on the total vacancy concentration because the close proximity of the growth interface and the high diffusivity of the vacancies will not allow large deviations from the equilibrium value. Due to the large excess of oxygen over nitrogen, it has been assumed that the equilibrium of reaction (III) is on the left-hand side near the melting point and so very little N_2 is available. As the temperature decreases, the

Fig. 5.18 Radial vacancy and Si interstitial distributions as derived from a FZ crystal grown with an axially varying nitrogen concentration. $C_{V0} = 8.8 \times 10^{12} \text{ at/cm}^3$ and $C_{I0} = 7.7 \times 10^{12} \text{ at/cm}^3$. The solid and dashed lines refer to simulation results. (After [5.113])

equilibrium gradually shifts to the right-hand side and more and more N_2 is generated. If the temperature at which N_2 starts to develop in sufficient quantities is below the vacancy aggregation temperature, the formation of voids is not suppressed. If the N_2 formation temperature is above the vacancy aggregation temperature, void formation depends on how much N_2 is available in relation to the vacancy concentration at the void nucleation temperature. The higher the N_2 formation temperature, the more N_2 is available to reduce the number of vacancies by reaction (I). According to reaction (III), the formation temperature of N_2 should increase with lower oxygen and higher nitrogen concentrations. Lower free vacancy concentrations and therefore lower aggregation temperatures result in voids of smaller size but higher density, in agreement with the experimental findings.

After void nucleation, the free vacancy concentration drops rapidly and the above reaction (I) reverses, giving $N_2V \rightarrow N_2 + V$, which slows down the decay of free vacancies. Thus, the N_2V -complex acts as an inter-reservoir for vacancies – its formation before void formation removes vacancies and its dissociation after void formation releases them again [5.90]. In conjunction with the lower vacancy aggregation temperature, this results in a notable increase in free vacancy concentration during this cool-down phase compared to nitrogen-free material (Fig. 5.19). As free vacancies are known to strongly favor the nucleation of oxygen precipitates, the latter effect gives a simple explanation for the observed strong enhancement of oxygen precipitation in nitrogen-doped CZ crystals (Sect. 5.4).

Fig. 5.19 Simulated variations in the vacancy concentration as a function of temperature for a nitrogen-doped and an undoped crystal

The remarkable variation in the void morphology as a function of the nitrogen content is still under discussion. A similar change in morphology is also known for oxygen precipitates. In this case, the effect can be interpreted in terms of the balance between the relaxation energy of the lattice strain and the interfacial energy. However, TEM investigations do not reveal any lattice strain around voids, and so another mechanism is required to explain the varying void morphology.

Boron

Boron doping affects the intrinsic point defect aggregation in a similar way to nitrogen doping, but much higher concentrations are required [5.119]. It was found that the COP region as well as the diameter of the OSF ring starts to shrink when the boron content exceeds roughly 5×10^{18} at/cm³ (Fig. 5.20). In contrast with nitrogen, OSF formation is not enhanced and the width of the OSF ring remains unchanged with increasing boron concentration. At around 10^{19} at/cm³, the COPs and the OSF ring disappear in the center of the crystal. Although detailed investigations into the behavior of L-pits in highly boron-doped silicon are still required, we can infer from the defect-free quality of pp+ epi wafers that L-pits are simultaneously suppressed by the high boron level (Sect. 5.3.1).

Dornberger et al. [5.67] suspected that changes in the equilibrium concentrations and diffusivities of intrinsic point defects in the presence of high boron concentrations would modify the transition value ξ_{tr} of the parameter V/G as a function of the boron content. Voronkov and Falster [5.81] also proposed a modification of equilibrium concentrations as a result of the shift

Fig. 5.20 Variation in the OSF ring diameter as a function of the boron concentration. (After [5.118])

in the Fermi level due to the high boron concentration. Based on this approach, the latter authors calculated a shift in the transition value ξ_{tr} which would account for the observed shrinkage of the void region. As with nitrogen doping, the ξ_{tr} shift entails the simultaneous appearance of L-pits in the outer crystal region and a shrinking void region, which is in conflict with experimental results. Another attempt by Sinno et al. [5.120] considers reversible reactions between boron and intrinsic point defects, in particular self-interstitials. The formation of BI and B₂I complexes consumes self-interstitials which would otherwise be annihilated by recombination. As recombination consumes the remaining self-interstitials, BI and B₂I start to dissociate again according to Le Chatelier's principle. As a result, the self-interstitial concentration increases, which shifts the point defect balance towards the interstitial-rich side, causing the void region to shrink. No comment is made about whether or not the model is also able to account for the suppression of L-pit formation by storing supersaturated self-interstitials in boron complexes.

Carbon

Carbon doping is also known to impact intrinsic point defect aggregation. It has been reported that the void region in the crystal center disappears upon carbon doping [5.57, 121], while the region of Si interstitial aggregates is widened; in other words, carbon does not inhibit the formation of L-pits/A-swirl. This behavior appears to be in line with the model put forward

in [5.109], which predicts an upward shift of ξ_{tr} for carbon doping and, in turn, an enlargement of the interstitial-rich region.

It was also found that carbon doping reduces the grown-in defect size [5.87, 122]. Although the size reduction is appreciable, the morphology of the voids is not changed, in contrast to the consequences of nitrogen doping. Only a tendency towards multiple void formation was observed. The thickness of the inner oxide layer was found to be similar to that of undoped crystals, which indicates that carbon doping has no influence on the growth of the inner oxide layer. As with boron, the effect on defect aggregation is only seen at significantly higher concentrations ($\approx 1 \times 10^{17}$ at/cm³) than for nitrogen.

At higher concentrations, carbon is known to enhance oxygen precipitation too [5.123, 124]. As carbon predominantly resides on substitutional sites, it is very unlikely that, as in the case of nitrogen doping, a higher residual vacancy concentration is responsible for the stronger oxygen precipitation. On the other hand, the small carbon atom exerts a local tensile strain on the surrounding lattice and attracts Si interstitials to form C_xI_y complexes. Thus, Si interstitials ejected into the lattice by growing oxygen precipitates are effectively removed and, in turn, further precipitate growth is not retarded by a build-up of Si interstitial supersaturation. The enhanced oxygen precipitation may also be related to heterogeneous nucleation at small carbon aggregates [5.125].

5.4 Formation of OSF Ring

The ring-like distributed OSFs are oxygen precipitates with platelet shapes that grow particularly large at the edge of the void region, and exceed a critical size necessary to create stacking faults during subsequent wafer oxidation there [5.126]. The critical radius of the grown-in platelets is ≈ 70 nm. The formation of OSFs can be suppressed if the cooling rate of the growing crystal is increased (this means, for example, that OSFs are not found in oxygen-doped FZ crystals [5.118] which have very high cooling rates) or if the oxygen content is decreased.

The peculiar ring-like distribution is a consequence of the well-known strong enhancement of oxygen precipitation by vacancies [5.39, 127]. The reason for this is that the absorption of vacancies allows the oxygen precipitate, which occupies twice as much volume as the corresponding silicon lattice, to nucleate and grow

without building up notable strain energy. As will be described below, the radially inhomogeneous oxygen precipitation is a consequence of a substantial radial inhomogeneity of the free vacancy concentration in contrast to the rather flat radial profile of oxygen.

The vacancy concentration, as pointed out previously, has its maximum at the center of the growing crystal after V-I recombination has ceased (Fig. 5.21). Therefore, the critical supersaturation for void formation is first reached at the crystal center at relatively high temperatures. Hence, the free vacancies are quickly consumed in this area. As the crystal cools, voids are also nucleated in the regions of lower initial vacancy concentration, meaning that vacancy consumption then also occurs further away from the crystal center. As the removal of vacancies is enhanced at higher temperatures, where the diffusivity is large, the ra-

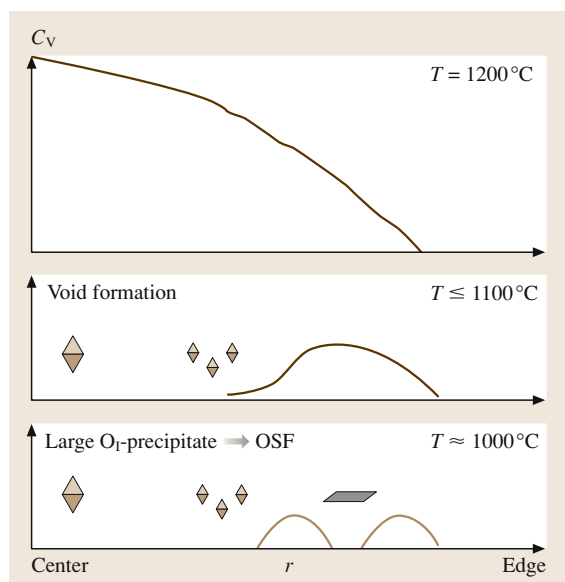

Fig. 5.21 Schematic evolution of the radial vacancy profile and accompanying void and large O_I -precipitate formation at decreasing temperatures

dial vacancy distribution finally drops to a minimum in the crystal center, and the maximum of the residual vacancies gradually moves toward the V/I boundary upon further cooling. Because of this shifted vacancy maximum, the first oxygen aggregates nucleate close to the V/I boundary on the vacancy-rich side. The relatively high nucleation temperature at this position results in larger sizes but lower densities for the corresponding grown-in oxygen precipitates compared to those nucleated at lower temperatures away from the V/I boundary. Consequently, they preferentially reach the critical size for OSF formation during subsequent

wafer oxidation. At sufficiently fast crystal cooling rates, the oxygen precipitates are nucleated at higher densities but smaller sizes and cannot grow to the critical size. Thus, OSF formation is prevented, in agreement with experimental findings. The same density/size effect is obtained if the oxygen content is lowered – similar to the behavior of voids – and so OSFs are also suppressed.

The nucleations of the first oxygen precipitates quickly results in the depletion of residual vacancies in their neighborhood. Thus, the previous vacancy maximum at the V–I boundary is then converted into a pronounced minimum which suppresses further nucleation in this area. As a result, two vacancy peaks with a region of large oxygen precipitates in-between is frozen in as the crystal cools down to room temperature (Fig. 5.21). Later on, when the wafers are subjected to further heat treatments, such as a nucleation step at 780°C followed by a growth step at 1000°C, new oxygen precipitates with high density are preferentially nucleated at the radial positions of the two remaining vacancy maxima. This results in a distinct profile for the interstitial oxygen concentration after these heat treatments. In the radial band where the large precipitates and the OSF ring are located, the interstitial oxygen concentration is only slightly reduced because further nucleation of precipitates during wafer heat treatment is suppressed there and the comparatively low density of precipitates does not consume much of the interstitial oxygen. On the other hand, the high density bands at the locations adjacent to the former vacancy peaks coincide with pronounced minima in the interstitial oxygen content.

Considerable changes in the widths and the radial positions of OSF rings are observed if the crystals are nitrogen-doped. With increasing nitrogen content, the outer and inner OSF ring boundaries are shifted towards the crystal center [5.90]. However, the shift is much larger for the inner OSF ring boundary, resulting in a significant widening of the OSF ring width (Fig. 5.22) until it extends over the entire crystal volume. This behavior was tentatively explained by a schematic model that takes into account the slower build-up of vacancy supersaturation due to the formation of N_2V complexes and the resulting lower void nucleation temperature. The model also predicts that the void and the OSF region overlap, roughly in the area between the inner boundary and the middle of the OSF ring, which is in agreement with experimental data (Fig. 5.23).

In contrast to nitrogen, carbon tends to suppress OSF formation. This is again an indication that the

Fig. 5.22 Variations of the outer and inner OSF ring boundaries as a function of the nitrogen concentration. (After [5.90])

mechanism of the effect of carbon is different. The above-mentioned idea of heterogeneous nucleation due

Fig. 5.23 Variations in the OSF ring width and its radial location in comparison to the variations of the COP and LLS boundaries along the crystal axis. The LLS defects were detected on the as-polished wafer surface, which detects only the larger voids, while the COP boundary was determined by LLS measurements after repeated SC1 cleaning, which enlarges the voids to above the LLS detection limit

to small carbon clusters may also explain this behavior. As heterogeneous nucleation needs less supersaturation, it prevails over homogeneous nucleation. Furthermore, the density of carbon clusters is much higher than that of homogeneously nucleated oxygen precipitates. Thus, the heterogeneously nucleated oxygen precipitates cannot grow to the critical size due to their large densities.

Diffusion in S

6. Diffusion in Semiconductors

Atomic diffusion in semiconductors refers to the migration of atoms, including host, dopant and impurities. Diffusion occurs in all thermodynamic phases, but the solid phase is the most important in semiconductors. There are two types of semiconductor solid phase: amorphous (including organic) and crystalline. In this chapter we consider crystalline semiconductors and describe the processes by which atoms and defects move between lattice sites. The emphasis is on describing the various conditions under which diffusion can occur, as well as the atomic mechanisms that are involved, rather than on tabulating data. For brevity's sake, we also focus on the general features found in the principal semiconductors from Groups IV, III–V and II–VI; IV–VI and oxide semiconductors are excluded from consideration. It is not surprising that most of the data available in this field relate to the semiconductors that are technologically important – they are used to fabricate electronic and optoelectronic devices. One unavoidable consequence of this technological need is that diffusion data tend to be acquired in a piecemeal fashion.

Diffusion describes the movement of atoms in space, primarily due to thermal motion, and it occurs in all forms of matter. This chapter focuses on atom diffusion in crystalline semiconductors, where diffusing atoms migrate from one lattice site to another in the semiconductor crystal. The diffusion of atoms and defects is at the heart of material processing, whether at the growth or post-growth stage, and control over diffusion

is the basis of process simulation and defect engineering. Such control calls for an understanding of the diffusion processes involved in a given situation. The needs of device technology have provided the main impetus for investigations into the diffusion of atoms in semiconductors. As the physical dimensions of devices have shrunk, the barriers to understanding diffusion mechanisms and processes in complex structures have greatly multiplied.

6.1 Basic Concepts

Consider a particle in a three-dimensional isotropic lattice which migrates by making jumps from one lattice site to a nearest neighbor site. If the distance between nearest neighbor sites is a and the particle makes n jumps in time t , then, assuming each jump is random (so the directions of successive jumps are independent of each other), the mean square displacement $\langle R^2 \rangle$ is equal to na^2 [6.1]. Fick's first law defines the associated diffusivity D to be $na^2/6t = \langle R^2 \rangle/6t = va^2/6$, where $v = n/t$ is the average jump rate of the particle. Taking the diffusion length as $2\sqrt{Dt}$, it follows that this is also equal to $2\sqrt{\langle R^2 \rangle/6}$. For $D = 10^{-12} \text{ cm}^2/\text{s}$, $t = 10^4 \text{ s}$

and $a = 2 \times 10^{-8} \text{ cm}$, the diffusion length is $2 \mu\text{m}$, $n = 1.5 \times 10^8$ jumps and the total distance na traveled by the particle is 3 cm . However, it turns out that in most diffusion mechanisms successive jumps are correlated, not random. The effect of nonrandom jumps is to decrease the diffusivity of the particle relative to what it would be if the jumps were random. Taking this correlation into account leads to $D = fva^2/6$, where $f (\leq 1)$ is the correlation factor [6.1], v is temperature-dependent and f may or may not be, depending on the particular situation. Overall, the temperature dependence of D is found to obey the Arrhenius relation $D = D_0 \exp(-Q/kT)$.

6.2 Diffusion Mechanisms

Two categories of diffusion mechanism are recognized: defect and nondefect. A simple example of the latter class is the simultaneous jumps of two adjacent atoms in order to exchange sites. There is a general consensus, however, that nondefect mechanisms do not play any significant role in semiconductor diffusion, although recently nondefect contributions have been proposed for self- and dopant diffusions in Si [6.2]. In the elemental semiconductors Si and Ge, vacancies and interstitials are the primary defects. In binary compound semiconductors (such as GaAs and ZnSe) there are two sublattices, the anion and cation, so there are vacancies and interstitials for each sublattice together with antisite defects on each sublattice. Further complexity arises due to the various states of ionization of the defects: the mobility of a defect depends on its charge state. The relative concentrations of the different charge states will be determined by the position of the Fermi level.

6.2.1 Vacancy and Interstitial Diffusion Mechanisms

In the Si lattice, a vacancy V_{Si} can migrate by a nearest neighbor Si atom jumping into the vacancy (in other words, the Si atom and V_{Si} have exchanged sites so that the Si atom has also migrated). Equally, a substitutional dopant atom can migrate by jumping into a V_{Si} at a nearest neighbor site. Similarly, in a binary semiconductor such as GaAs, Ga atoms can migrate over the Ga sublattice via jumps into nearest neighbor Ga vacancies, as can dopant atoms substituting into the Ga sublattice. Anti-site defects can diffuse by jumping into vacancies

in the same sublattice, such as the As anti-site defect in GaAs, As_{Ga} , diffusing by jumps into Ga vacancies. For self-interstitials, such as Si_i or Ga_i , their concentrations are sufficiently small for neighboring interstitial sites to always be empty, which means that the occupancy of nearest neighbor sites is not a factor when determining jump rates. If a self-interstitial, such as Si_i , pushes a Si atom on a normal lattice site into an interstitial site instead of jumping into a neighboring interstitial site, and therefore replaces the displaced Si atom, the process is known as the “interstitialcy mechanism”. This concept extends to a substitutional dopant atom forming a pair with a self-interstitial, which then migrates with the dopant atom, alternating between substitutional and interstitial sites. It is also possible for point defects to form complexes which can diffuse as a single entity. Examples are the Frenkel pair $V_{\text{Si}}\text{Si}_i$, di-vacancies such as $V_{\text{Ga}}V_{\text{Ga}}$ or $V_{\text{Ga}}V_{\text{As}}$, and the defect pair formed between a substitutional dopant atom and an adjacent vacancy.

6.2.2 The Interstitial–Substitutional Mechanism: Dissociative and Kick-Out Mechanisms

The interstitial–substitutional diffusion mechanism arises when a dopant species Z occupies both interstitial and substitutional sites, represented by Z_i and Z_s respectively, and diffusion is restricted to jumps of Z_i . In this case, we may ask how the Z_s concentration $[Z_s]$ is linked to the Z_i migration. Consider the diffusion of Z in Si. The dissociative mechanism (also known as the Frank–Turnbull mechanism) is based on the defect

interaction

and application of the law of mass action (LMA) leads to $[Z_i][V_{Si}] \propto [Z_s]$. In the kick-out mechanism, the defect interaction is

and therefore $[Z_i] \propto [Z_s][Si_i]$ ($[Si_s]$ is omitted because it is effectively constant). In order to sustain growth in $[Z_s]$ by either mechanism, it is clearly necessary to have either a supply of V_{Si} or a means of removing Si_i . For simplicity, neutral charge states have been assigned to all of the defects in these two interactions. A detailed treatment of the kick-out mechanism has been given by Frank et al. [6.3]. For in-diffusion of Z, the Frank–Turnbull mechanism consumes vacancies and will therefore tend to reduce the local vacancy concentration, whereas the

local self-interstitial concentration will be enhanced by the kick-out mechanism. Out-diffusion of Z reverses the effects on the native defect concentrations.

6.2.3 The Percolation Mechanism

The percolation mechanism [6.4] was proposed to explain group V dopant diffusion in Si at high dopant concentrations (in excess of $\approx 1\%$). At low concentrations diffusion is via dopant- V_{Si} pairs. As the dopant concentration increases, regions occur in the Si lattice where the proximity of the dopant atoms enhances the mobility and concentration of the V_{Si} . Within this network the diffusivity of dopant- V_{Si} pairs is thereby also enhanced so that the dopant diffusivity increases overall. The percolation network only forms once the dopant concentration exceeds a certain critical value. In principle this mechanism could extend to other highly doped materials.

6.3 Diffusion Regimes

The mobility of a native defect and/or dopant atom reflects the physical and chemical environment under which diffusion is occurring. Two types of environment arise: conditions of chemical equilibrium and those of chemical nonequilibrium. Diffusion in temperature gradients is excluded – only isothermal conditions are considered.

6.3.1 Chemical Equilibrium: Self- and Isoconcentration Diffusion

Chemical equilibrium means that the concentrations of all chemical components, including native defects, are uniform throughout the semiconductor, and where appropriate (such as in a compound material), the solid is in equilibrium with the ambient vapor of the components so that the level of nonstoichiometry is defined. Experimentally this requires diffusion to be carried out in a sealed system. Self-diffusion refers to the diffusion of the host atoms, such as Si atoms diffusing in the Si lattice. Isoconcentration diffusion describes the diffusion of dopant atoms when the same dopant concentration is uniform throughout the sample, such as for As diffusion in Si for a constant As doping level. In either case, diffusion can only be observed if some of the particular diffusing atoms are tagged, such as by using a radioisotope or an isotopically enriched diffu-

sion source. The diffusivity of a tagged or tracer species is related to the concentration of the native defect that provides the diffusion path, and the self-diffusivity (the diffusivity of the tracer) is always significantly smaller than the associated defect diffusivity. Specific relations can be found in Shaw [6.5]. A diffusion flux of the tracer arises from a tracer concentration gradient, which is not to be confused with a chemical concentration gradient.

6.3.2 Chemical Diffusion (or Diffusion Under Nonequilibrium Conditions)

This category contains all of the diffusion phenomena that are of technological interest and importance. In this case, diffusion occurs due to spatial gradients in the concentrations of the chemical components in the material, which are in turn caused by departures from equilibrium: the diffusion processes are attempting to either restore or achieve equilibrium.

Chemical Self-Diffusion

Chemical self-diffusion describes the process whereby a compound semiconductor changes from one level of nonstoichiometry to another through changes in the native defect populations. These changes can arise due to a change in the ambient partial pressure of one

of the components (that of As in the case of GaAs for example), or through a change in temperature under a defined or controlled component partial pressure. Good examples are provided by II–VI semiconductors [6.6] and in particular $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$ [6.7], where p- to n-type conversion is used to form p–n junctions by annealing in Hg vapor. Changes in the native defect concentrations can also lead to an increased dopant diffusivity; an increase in the vacancy concentration will enhance any diffusivity based on a vacancy mechanism for instance.

Dopant Diffusion

Suppose we have a dopant diffusing into the semiconductor from a source located at an external surface (such as a surface layer) or in an external phase (such as a gas or vapor). The existence of the dopant concentration gradient can lead to various effects which can influence the dopant flux. For example, if a dopant diffuses via a vacancy mechanism, then at any position in the diffusion region the increase in the dopant concentration requires a supply of vacancies, so that to maintain local defect equilibrium there must also be an associated vacancy flux. If the dopant controls the position of the Fermi level, then the concentrations of ionized native defects will increase or decrease, depending on their charge state, relative to their intrinsic concentrations (the Fermi-level effect). This means that the concentrations of native defects of opposite (the same) polarity to the dopant will be increased (decreased). Increases in the concentrations of ionized native defects due to Zn, Si or Te diffusion into GaAs/GaAlAs superlattice structures explain the disordering of the superlattices [6.8]. Usually a substitutional dopant atom will have a different size to that of the host atom it replaces. This size difference creates a local mechanical strain which in turn can cause changes in the local concentrations of native defects as well as to jump rates and hence dopant diffusivity [6.9]. If the strain is large enough, misfit dislocations will be generated [6.10], otherwise there will be a strain energy gradient matching the dopant concentration gradient which can enhance or retard the dopant flux [6.11]. More recently a new scenario has emerged: dopant diffusion in strained epilayers. Whether diffusion is enhanced or retarded depends on several poorly understood parameters [6.12]. However, significant effects are found, such as the decrease in the B diffusivity in strained $\text{Si}_{1-x}\text{Ge}_x$ epilayers by a factor of ≈ 10 as the strain increased from zero to 0.64 [6.13].

Compositional Interdiffusion (CID)

Compositional interdiffusion describes diffusion across the interface separating two materials of different chemical composition. Chemical composition here refers to major components; dopants and deviations from stoichiometry are excluded. CID can be exploited when making graded bandgap structures and during material preparation, such as in $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$, where an alternating sequence of HgTe and CdTe epilayers of appropriate thicknesses are first grown and then interdiffused. CID can also pose problems in the fabrication of multiple quantum wells and superlattice structures when sharp boundaries are necessary. In particular, donor or acceptor dopant diffusion into GaAs-based superlattices can cause essentially complete intermixing on the cation sublattice [6.8]. This phenomenon is also known as diffusion-induced disorder. B or As doping also results in rapid intermixing at a Si/Ge interface [6.14].

Transient Enhanced Diffusion (TED)

Ion implantation is often the preferred way to achieve a doped layer. The implantation process does however create a significant amount of lattice damage so that a subsequent anneal stage is needed in order to achieve full electrical activity of the implanted dopant and recovery of the lattice damage. During the implantation process, the implant ions create collision cascades of vacancies and self-interstitials (an excess of native defects). The post-implant anneal serves to remove or reduce this excess. In addition to vacancy/interstitial recombination, the excess native defects can interact to form clusters (which also may contain implant ions as well as residual impurities) and extended defects, such as dislocation loops. At the start of the post-implant anneal, the local concentrations of vacancies and self-interstitials in the implant region can greatly exceed equilibrium values and therefore enhance the implant ion diffusivity in the implant region. As annealing proceeds the excess concentrations will diminish and will be reflected in a diminishing dopant diffusivity until values appropriate to local equilibrium are reached. This temporary enhancement in the dopant diffusivity is known as TED. The topic is a complex one to analyze quantitatively and detailed consideration of the issues involved in the case of B implants in Si can be found in the review by Jain et al. [6.15]. In the fabrication of shallow p–n junctions using ion implants and rapid thermal annealing (RTA), TED can determine the lower limit to junction depth. TED of B in Si can be reduced with coimplants of Si prior to RTA [6.16]. TED of Be and Si

in GaAs has also been discussed [6.17]. Some workers use the term **TED** to describe the enhanced diffusivity of a dopant, incorporated during growth, which occurs when the structure is annealed at a higher temperature than the growth temperature, such that there is an initial supersaturation of the relevant native defects at the anneal temperature.

Segregation, Gettering, Precipitation and Clustering

A variety of important scenarios arise, involving many of the above regimes, during growth and/or thermal processing stages of materials and structures. The segregation of acceptor dopants in InP [6.18] and in III–V heterostructures [6.19, 20] has been observed and modeled. The segregation (or accumulation) due to diffusion of the dopant is in effect a partitioning process to preferred (higher solubility) regions within the layer structure. Gettering describes the segregation, or clean-up, of a fast-diffusing impurity from the active regions of a device structure. Such impurities are typically Group IB and transition metals and are incorporated either during growth or during subsequent processing. Gettering sites in Si are provided by O precipitates, self-ion implant damage layers and nanocavities [6.21]. In contrast, Group IB impurities are gettered in $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ by regions of high cation vacancy concentration [6.22].

Precipitation occurs when a species – whether native defect, dopant or impurity – becomes supersaturated, and in order to achieve its equilibrium concentration the species excess is removed by the formation of precipitates within the host lattice. A self-interstitial or vacancy excess can be removed through the nucleation of dislocation loops, stacking faults or voids, which then provide sites for the precipitation of the remaining excess. In the case of a dopant, impurity or nonstoichiometric excess, nucleation of a precipitate can be spontaneous (homogeneous) or heterogeneous. The latter occurs at the site of an impurity atom (for example, C atoms in Si serve as nucleation centers for the precipitation of O) or at dislocations, giving rise to the term “decoration”. Growth of any precipitate proceeds via diffusion of the particular species from solution in the matrix to the precipitate and is generally diffusion-limited. Invariably local stress fields will be present which influence the diffusion and, if present initially, they may also play a role in the nucleation stage. The precipitation of O impurities in Si presents a unique case study because of the high [O], its technological importance and its complexity [6.23, 24]. The rather simpler case of B precipitation in Si has

been described by Solmi et al. [6.25]. A cluster (or agglomerate) refers to a configuration of at least a few dopant atoms (with or without associated native point defects) or host species. Solmi and Nobili [6.26] have identified $(2\text{As}_{\text{Si}} - \text{V}_{\text{Si}})^0$ and $(4\text{As}_{\text{Si}} - \text{V}_{\text{Si}})^+$ clusters in heavily As-doped Si. Heavy C doping [6.27] and B implants [6.28] in Si give rise to self-interstitial clusters with C and B respectively. In Si, according to Ortiz et al. [6.29], if the number of self-interstitials in a cluster exceeds ≈ 10 there is a transition to a {113} defect.

6.3.3 Recombination-Enhanced Diffusion

The local energy released in the nonradiative recombination of excess free carriers can help a diffusing species to surmount the energy barrier separating it from an adjacent lattice site – in other words, the energy barrier facing a jump is effectively reduced. This situation is important in the degradation of performance of device structures which utilize high excess minority carrier concentrations, such as light-emitting and laser diodes.

6.3.4 Surface Effects

The concentrations of native point defects within the bulk can be altered by surface processes. In the case of Si it is well known that during surface oxidation or nitridation there is injection of Si interstitials or of vacancies respectively. All diffusants can therefore be affected during the duration of the process. Ion beam milling causes the injection of Hg interstitials into $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ in sufficient quantities to effect p- to n-type conversion.

6.3.5 Short Circuit Paths

The existence of dislocations and subgrain boundaries in single-crystal materials generally provides high diffusivity routes for all atomic species relative to the surrounding matrix. Care is always needed when evaluating experimental data to ensure that bulk diffusion is not being masked by short circuit paths [6.30]. In the case of polycrystalline Si, the grain boundaries may provide high diffusivity routes, as in the cases of As and B [6.31], or retard diffusion, as for Au [6.32]. The situation is a complex one, as grain growth also occurs during any anneal. Kaur et al. [6.33] have provided a comprehensive account of short circuit path diffusion.

6.4 Internal Electric Fields

When the dopant concentration is large enough to make the diffusion zone electrically extrinsic, free carriers from the dopant, due to their much higher mobility, will diffuse ahead of the parent dopant atoms. This separation creates a local electric field whose direction is such as to pull the dopant atoms after the free carriers (and also to pull the free carriers back). Provided that the diffusion length $> \approx$ six Debye screening lengths (typically $\approx 10^2$ nm), the diffusion zone can be regarded as electrically neutral (the space charge density is negligible) [6.34]. In this situation the local electric field E is given by $-(kT/en)(\partial n/\partial x)$ for an ionized donor dopant diffusing parallel to the x -axis, and nondegenerate conditions apply: k , T , e and n are Boltzmann's constant, the absolute temperature, the electronic charge and the free electron concentration respectively. E exerts a force on each ionized donor (D^+) parallel to the x -axis, creating a local donor flux $-(D(D^+)/n)(\partial n/\partial x)$ due to drift in the electric

field: $D(D^+)$ is the donor diffusivity [6.35]. This drift flux adds to the diffusion flux, $-D(D^+)\partial[D^+]/\partial x$, to give the total donor flux at any position in the diffusion region, so that the donor flux in this case is increased due to E . E will also cause drift of any other charged species.

Internal electric fields can arise in other circumstances such as in depletion layers where E must be calculated from Poisson's equation, in graded bandgap structures [6.11, 36], and at the interfaces of heterostructures. Cubic II–VI and III–V strained layer heterostructures grown on the $\{111\}$ direction are piezoelectric and typical strains from lattice mismatch of $\approx 1\%$ can give $E \approx 10^5$ V/cm in the absence of free carrier screening [6.37]. In wurtzite heterostructures based on the Ga, In nitrides, even higher fields are found ($E \approx 10^6$ V/cm) due to piezoelectric and spontaneous polarization [6.38]. These fields can be important in CID and chemical self-diffusion.

6.5 Measurement of Diffusion Coefficients

6.5.1 Anneal Conditions

Accurate control of sample temperature and ambient are essential if controlled and reproducible results are to be obtained in a diffusion anneal. Depending on the time spent at the anneal temperature, the warm-up and cool-down times may also be important. An appropriate choice of ambient is needed to preserve the sample surface (to avoid evaporation, surface melting or alloying with the dopant source for example). For compound semiconductors it is necessary to define the level of non-stoichiometry by controlling the ambient partial pressure of one of the components, such as As for GaAs or Hg for $Hg_{1-x}Cd_xTe$. If the dopant is in an external phase, knowledge of the phase diagram of all of the components is required [6.1, 35]. Control over partial pressure is best achieved in a sealed system, typically a fused silica ampoule. Annealing in a vertical or horizontal resistance-heated furnace requires a minimum anneal time of 30 to 60 min in order to avoid uncertainties due to warm-up and cool-down. The drive to shallow dopant profiles has been facilitated through rapid thermal annealing (RTA) techniques. These are based on radiant heating of the sample, and linear heating rates of $100\text{--}400^\circ\text{C/s}$ with cooling rates of up to 150°C/s are available. RTA however precludes the use of a sealed

system and, in this case, a popular means of preventing surface deterioration is to seal the sample with an inert, impervious capping layer, made of silicon nitride for example.

6.5.2 Diffusion Sources

Consideration is limited to planar samples with diffusion normal to a principal face. This is a common situation and diffusion of a dopant or tracer species can take place from: (i) a surrounding vapor or gas phase; (ii) a surface layer, which may be evaporated, chemically deposited (CVD) or a spun-on silicate glass, all incorporating the diffusant; (iii) epilayers containing the diffusant, which may provide the external surface or be buried within the epitaxial structure; (iv) ion implants of a dopant either directly into the sample surface or into a thin surface layer so as to avoid lattice damage. It is obviously desirable that negligible diffusion occurs prior to reaching the anneal temperature when the diffusant is incorporated into an epilayer. In self-diffusion experiments the tracer can be a radiotracer or an isotopically enriched species. A key requirement for either form of tracer is availability, and a radiotracer must have a half-life that is long enough for the experiments to be carried out.

6.5.3 Profiling Techniques

Determining the spatial distribution of a diffusant for various anneal times is fundamental to obtaining its diffusion coefficient or diffusivity. Most methods are destructive, as they generally require a bevel section through the diffusion zone or the sequential removal of layers. The two broad profiling categories are electrical and species-specific. Electrical methods are primarily the p–n junction method, spreading resistance and capacitance–voltage profiling. Limitations of the electrical methods are: (i) assumptions are needed to link the electrical data to the diffusant (for example, that the diffusant is the only electrically active center and that it is fully ionized); (ii) the assumption that the anneal temperature defect situation is “frozen-in” during cool-down. Electrical methods are the most direct means of measuring chemical self-diffusivities and can readily detect changes in host concentrations of < 1 part in 10^4 . Species-specific (chemical element or isotope) profiling means that the chemical concentration of the diffusant is determined regardless of its location(s) in the lattice and of its electrical state. Profiling of the diffusant using a radiotracer has been widely used [6.39], but in the past decade or so secondary ion mass spectrometry (SIMS) has become what is essentially the standard procedure for diffusant profiling. This is because SIMS can measure diffusant concentrations within the range 10^{16} to 10^{22} cm $^{-3}$ with spatial resolutions at best of several nanometers per decade (of concentration). Primary factors determining the resolution are progressive roughening of the eroded surface and “knock-on” effects due to the probing ion beam displacing the diffusant to greater depths. A further problem may arise when the atomic mass of a dopant is close to that of the host species.

Nondestructive profiling techniques applicable to CID in quantum well and superlattice structures utilize either high-resolution X-ray diffraction

(HRXRD) [6.40] or photoluminescence (PL). The detail in the X-ray diffraction patterns reflects the CID profiles at the interfaces and can also reveal the presence of strain in the structures. The use of PL requires the presence of optically active centers in the quantum well. CID changes the shape and depth of the quantum well, which in turn changes the photon energies in the luminescence spectra. HRXRD and PL can also be combined. A particular advantage of these techniques is that they allow successive anneals to be performed on the same sample.

6.5.4 Calculating the Diffusion Coefficient

Once a planar concentration profile has been obtained, the first step is to see if the profile can be fitted to a solution of Fick’s second law. The simplest solution occurs for a diffusivity D independent of the diffusant concentration (c), for a constant surface concentration c_0 and a diffusion length \ll the layer or sample thickness. The solution is $c = c_0 \operatorname{erfc}[x/2\sqrt{(Dt)}]$ [6.1]. If the profile is not erfc, it may be because D varies with c , and D (as a function of c) can be obtained by a Boltzmann–Matano analysis [6.35]. It is important to recognize that the erfc or Boltzmann–Matano solutions are only valid provided c_0 does not change with time and that c/c_0 versus x/\sqrt{t} for profiles at various t reduce to a single profile. More complex situations and profiles require numerical integration of the appropriate diffusion equation(s) and matching to the experimental c versus x profile; in other words a suitable model with adjustable parameters is used to simulate the observed profiles. The interpretation of HRXRD and/or PL data provides a good example of a simulation scene in which an assumed D , either c -dependent or c -independent, is used to calculate the resulting CID profile and its effect on the X-ray patterns and/or PL spectra. Whereas SIMS can observe diffusivities as low as $\approx 10^{-19}$ cm 2 /s, the HRXRD limit is $\approx 10^{-23}$ cm 2 /s.

6.6 Hydrogen in Semiconductors

Hydrogen is a ubiquitous element in semiconductor materials and can be incorporated either by deliberate doping or inadvertently, at significant concentrations, during growth and/or in subsequent surface treatments where organic solvents, acid or plasma etching are used. H is known to passivate electrically active centers by forming complexes with dopants and native defects as well as by bonding to the dangling bonds at extended

defects. Such interactions may well affect the diffusivities of the dopant and native defect. This expectation is realized in the case of O in Si, where the presence of H can enhance O diffusivity by two to three orders of magnitude [6.41]. Ab initio calculations show that, at least in the Group IV and III–V semiconductors, H is incorporated interstitially in the three charge states, H^+ , H^0 and H^- , with the Fermi level controlling

the relative concentrations. In addition to interactions with dopant atoms and native defects, H_2 molecules also form. Mathiot [6.42] has modeled H diffusion in terms of simultaneous diffusion by the three interstitial charge

states with the formation of immobile neutral complexes. In polycrystalline Si, the grain boundaries retard H diffusion, so H diffuses faster in the surrounding lattice than in the grain boundary.

6.7 Diffusion in Group IV Semiconductors

Diffusants divide into one of five categories: self-, other Group IVs, slow diffusers (typically dopants from Groups III and V), intermediate diffusers and fast diffusers. The materials of interest are Ge, Si, Si/Ge alloys and SiC. A particular feature is that self-diffusion is always slower than the diffusion of other diffusants. With the exception of SiC, which has the zinc blende structure, as well as numerous polytypes (the simplest of which is the wurtzite, $2H-SiC$, form), the other members of this group have the diamond lattice structure.

6.7.1 Germanium

The evidence to date identifies the dominant native defect in Ge as the singly ionized vacancy acceptor, V_{Ge}^- [6.43], which can account for the features found in self-diffusion and in the diffusivities of dopants from groups III and V. The self-diffusivity, relative to the electrically intrinsic value, is increased in n-type Ge and decreased in p-type as expected from the dependence of $[V_{Ge}^-]$ on the Fermi level. In intrinsic Ge the best parameters for the self-diffusivity are $D_0 = 13.6 \text{ cm}^2/\text{s}$ and $Q = 3.09 \text{ eV}$, from Werner et al. [6.44], because of the wide temperature range covered (535–904 °C). The diffusivities of donor dopants (P, As, Sb) are very similar in magnitude, as are those for acceptor dopants (Al, In, Ga). The acceptor group diffusivities, however, are very close to the intrinsic self-diffusivity, whereas those for the donor group are 10^2 to 10^3 times larger. Li is a fast (interstitial) diffuser with a diffusivity exceeding the donor group diffusivities by factors of 10^7 to 10^5 between 600 and 900 °C, whereas Cu [6.45] and Au [6.46] are intermediate (dissociative) diffusers.

6.7.2 Silicon

Si stands alone due to the intensive investigations that have been lavished on it over the past 50 years. In the early days diffusion data yielded many perplexing features. Today the broad aspects are understood along with considerable detail, depending on the topic. Diffusion in Si covers many more topics than arise in any other semi-

conductor and it is still a very active area of R & D. It is now recognised that, apart from foreign purely interstitial species, self-interstitials, Si_i , and vacancies, V_{Si} , are involved in all diffusion phenomena. So far the best self-diffusion parameters obtained for intrinsic Si are $D_0 = 530 \text{ cm}^2/\text{s}$ and $Q = 4.75 \text{ eV}$ in the temperature range 855–1388 °C [6.47]. Two distinct facets of self- and dopant diffusion in Si are: (a) the diffusivity has two or three components, each with differing defect charge states; (b) the diffusivity reflects contributions from both Si_i and V_{Si} [6.2, 43, 48, 49]. Thus the Si self-diffusivity is determined by Si_i and V_{Si} mechanisms and by three separate defect charge states: neutral (0), positive (+) and negative (−). Identifying which charge state goes with which defect remains a problem. For the common dopants (B, P, As and Sb), B and P diffuse primarily via the Si_i defect, As diffuses via both Si_i and V_{Si} defects, whereas Sb diffuses primarily via V_{Si} . Two defect charge states are involved for B (0, 1+), As (0, 1−) and Sb (0, 1−), and three for P (0, 1−, 2−). The situation for Al [6.50], Ga [6.9] and In [6.51] has Si_i dominant for Al and In diffusion whereas both Si_i and V_{Si} are involved for Ga. The associated charge states are Al (0, 1+), Ga (0, 1+) and In (0). The diffusivities of the Group V donor dopants (P, As, Sb) lie close to each other and are up to a factor of ≈ 10 greater than the self-diffusivity. The acceptor dopants (B, Al, Ga, In) also form a group with diffusivities that are up to a factor of $\approx 10^2$ greater than the donor dopants. A recently observed interesting feature is that the diffusivities of B and P in intrinsic material depend on the length of the anneal time, showing an initial change until reaching a final value [6.52]. This time effect is attributed to the time needed for equilibration of the V_{Si} and Si_i concentrations at the anneal temperature.

The data presented by Tan and Gösele [6.43] show that Au, Pt and Zn are intermediate (kick-out) diffusers and that H, Li, Cu, Ni and Fe are fast interstitial diffusers. Recent evidence shows that Ir diffusion occurs via both kick-out and dissociative mechanisms [6.53]. To provide some perspective: at 1000 °C the diffusivity of H is $\approx 10^{-4} \text{ cm}^2/\text{s}$ compared to a self-diffusivity

of $8 \times 10^{-17} \text{ cm}^2/\text{s}$. C and O are important impurities because, though electrically neutral, they occur in high concentrations and can affect the electrical properties. Although O occupies interstitial sites and diffuses interstitially it should be classed as an intermediate diffuser because a diffusion jump entails the breaking of two Si–O bonds. C has a diffusivity that is a little larger than those of Group III dopants: its mechanism is unresolved between the “kick-out” mode or a diffusing complex comprising a Si_i and a substitutional C.

6.7.3 $\text{Si}_{1-x}\text{Ge}_x$ Alloys

Si and Ge form a continuous range of alloys in which there is a random distribution of either element as well as a continuous variation of bandgaps. The alloys have attracted considerable interest from a device perspective and are usually prepared as epilayers on Si substrates so that the epilayer will generally be in a strained state. Diffusivity data are sparse and, in the case of dopants, limited to B, P and Sb. One might expect that the diffusivity $D(Z)$ of dopant Z would increase continuously as x goes from 0 to 1 at any given temperature below the melting point of Ge. However, in the case of B, $D(\text{B})$ hardly varies for $x \lesssim 0.4$; even so, $D(\text{B})$ increases by a factor $\approx 10^3$ from $\approx 10^{-15} \text{ cm}^2/\text{s}$ in traversing the composition range at 900°C [6.54, 55]. $D(\text{P})$ increases by a factor of ≈ 4 for x values between 0 and 0.24, only to show a decrease at $x = 0.40$ [6.55]. Limited data suggest that $D(\text{Sb})$ rises continuously across the composition range, increasing by a factor $\approx 10^6$ at 900°C [6.56]. Surface oxidation enhances $D(\text{B})$ and $D(\text{P})$, indicating that the diffusivities are dominated by a self-interstitial mechanism, whereas $D(\text{Sb})$ is reduced by surface oxidation, pointing to a vacancy mechanism. Compressive strain retards $D(\text{B})$ whereas tensile strain gives a marginal enhancement [6.55]. Compressive strain enhances $D(\text{P})$ and $D(\text{Sb})$ [6.57]. Overall, some disagreement exists between different workers about the behavior of $D(Z)$, which may well stem from difficulties with characterizing the experimental conditions. Compositional interdiffusion has been characterized at the interface between Si and layers with $x < 0.2$ [6.58].

6.7.4 Silicon Carbide

Its large bandgap, high melting point and high dielectric breakdown strength make SiC a suitable material for devices intended for operation at high temperatures and high powers. It also has potential optoelectronic appli-

cations. Characterizing the material is complicated, as SiC occurs in a range of polytypes (different stacking sequences of close packed layers). Common polytypes are the cubic zinc blende phase 3C-SiC and the hexagonal phases 2H-SiC (wurtzite), 4H-SiC and 6H-SiC . This combination of high melting point, polytypism and variations in stoichiometry makes it difficult to measure diffusivities. Typical diffusion anneal temperatures for acceptor (B, Al, Ga) and donor (N, P) dopants are in the range $1800\text{--}2100^\circ\text{C}$. Ab initio calculations for single vacancies and anti-sites in 4H-SiC [6.59] found the Si_C and C_Si anti-sites to be both neutral and therefore generally inactive (electrically and optically). The C vacancy is amphoteric with charge states ranging from $2+$ to $2-$. The Si vacancy is also amphoteric with charge states ranging from $1+$ to $3-$. Similar calculations for self-interstitials in 3C-SiC [6.60] predict divalent donor behavior for both Si and C interstitials. Bockstedte et al. [6.61] have calculated, using ab initio methods, the activation energies Q for self-diffusion in 3C-SiC by vacancies and self-interstitials. Generally Q is smaller for self-interstitials but the defect charge state is also an important factor. The Si vacancy is predicted to be metastable, readily transforming to the stable complex $\text{V}_\text{C}-\text{C}_\text{Si}$; the complex $\text{V}_\text{Si}-\text{Si}_\text{C}$ is unstable, reverting to V_C .

The Si and C self-diffusivities, $D(\text{Si})$ and $D(\text{C})$, respectively, were measured between 1850 and 2300°C by Hong et al. ([6.62] and references therein) in both 3C-SiC and 6H-SiC . The ratio $D(\text{C})/D(\text{Si})$ was ≈ 650 in 3C-SiC and ≈ 130 in 6H-SiC . N doping increased $D(\text{Si})$ and reduced (marginally) $D(\text{C})$. This behavior suggests that native acceptors are important for Si self-diffusion and that native donors are only marginally involved in determining $D(\text{C})$. Of particular interest is that, between the two polytypes, the self-diffusivities in 6H-SiC exceeded those in 3C-SiC by less than a factor of ≈ 3 . This suggests that diffusivities are insensitive to the particular polytype. More recent measurements of $D(\text{C})$, between 2100 and 2350°C , in 4H-SiC found diffusivities that were $\approx 10^5$ times smaller than the earlier results for 3C-SiC and 6H-SiC , mainly because of differences in D_0 [6.63]. There is currently no explanation for these huge differences and the question of the reliability of self-diffusivity data must be considered.

Earlier work by Vodakov et al. [6.64] found that the diffusivity of B in six different polytypes of SiC, excluding 3C-SiC , varied by $\leq 30\%$, not only for diffusion along the c -axis but also perpendicular to it. The diffusivities of some common dopants have been sum-

marized by *Vodakov* and *Mokhov* [6.65]. B diffusion mechanisms in 4H and 6H-SiC have been discussed by *Usov et al.* [6.66]. A recent finding is that an SiO₂ layer on the surface of 6H-SiC greatly enhances B diffusion [6.67], yielding a diffusivity of $\approx 6 \times 10^{-16} \text{ cm}^2/\text{s}$

at 900 °C. This compares to a temperature of $\approx 1400 \text{ °C}$ (extrapolated) for the same diffusivity without an SiO₂ layer. Electric fields of $\approx 10^6 \text{ V/cm}$ have been found in 4H/3C/4H-SiC quantum wells due to spontaneous polarization in the 4H-SiC matrix [6.68].

6.8 Diffusion in III–V Compounds

The III–V binary compounds are formed between the cations B, Al, Ga, In and the anions N, P, As and Sb. Mutual solubility gives rise to the ternaries, such as Al_{1-x}Ga_xAs, and to the quaternaries, such as In_{1-x}Ga_xAs_{1-y}P_y. The B compounds offer little more than academic interest, whereas the rest of the III–V family are important materials in both electronic and optoelectronic devices. The nitrides all have the wurtzite structure, with the remaining compounds possessing the zinc blende structure. In view of the wide range of binaries, ternaries, and so on, it is not surprising that diffusivity measurements have focused mainly on those compounds relevant to devices: essentially GaAs and GaAs-based materials. An important characteristic of these compounds is the high vapor pressures of the anion components; it is the variations in these components that lead to significant changes in levels of nonstoichiometry. This means that a proper characterization, at a given temperature, of any diffusivity must specify the doping level and the ambient anion vapor pressure during the anneal: the latter determines native defect concentrations in intrinsic samples, and both factors have equal importance in controlling the concentrations under extrinsic conditions. On both the anion and the cation sublattices, the possible native point defects are the vacancy, the self-interstitial and the anti-site and all can occur in one or more charge states.

and Ga_i²⁺ could dominate at high doping levels. Between 800 and 1200 °C the Arrhenius parameters for $D(\text{Ga})$ are $D_0 = 0.64 \text{ cm}^2/\text{s}$ and $Q = 3.71 \text{ eV}$ in intrinsic GaAs under a partial As₄ vapor pressure of $\approx 1 \text{ atm}$. The situation for As self-diffusion is less clear, but the evidence points to the dominance (in the diffusion process) of the neutral As interstitial over the As vacancy (the supposedly dominant native defect, the As anti-site, is not involved). Data have been obtained for both Ga and Sb self-diffusion in intrinsic GaSb under Ga- and Sb-rich conditions. There is a conflict between the results obtained with bulk material and those from isotope heterostructures (see [6.70] and references therein). *Shaw* [6.70] concluded that the defects involved in Ga self-diffusion were the Frenkel pair Ga_iV_{Ga} and V_{Ga} even though the Ga anti-site Ga_{Sb} appears to be the dominant native defect. Two parallel mechanisms were also identified for Sb self-diffusion, namely one due to the defect pair Sb_iV_{Ga} and the second due to either to the mixed vacancy pair V_{Ga}V_{Sb} or to the triple defect V_{Ga}Ga_{Sb}V_{Ga}. Reliable results for $D(\text{Ga})$ in intrinsic GaP under a partial vapor pressure (P_4) of $\approx 1 \text{ atm}$ are also available [6.71]: between 1000 and 1190 °C the Arrhenius parameters for $D(\text{Ga})$ are $D_0 = 2.0 \text{ cm}^2/\text{s}$ and $Q = 4.5 \text{ eV}$. Data on the effects of doping and changing partial pressure are lacking.

6.8.1 Self-Diffusion

Self-diffusivity data are limited to the Ga and In compounds [6.35, 69], and even here systematic measurements are restricted to GaAs [6.43, 69] and GaSb ([6.70] and references therein). For GaAs, early evidence (based largely on CID in AlGaAs structures) concluded that the Ga self-diffusivity $D(\text{Ga})$ was determined by the triply ionized Ga vacancy V_{Ga}^{3-} and doubly ionized Ga interstitial Ga_i^{2+} . More recent and direct measurements of $D(\text{Ga})$ in Ga isotope heterostructures identified the three vacancy charge states V_{Ga}^{2-} , V_{Ga}^{1-} and V_{Ga}^0 as being responsible for $D(\text{Ga})$ in intrinsic and lightly doped GaAs; the possibility remains that V_{Ga}^{3-}

6.8.2 Dopant Diffusion

Most of the data on dopant diffusion in the III–Vs refer to GaAs [6.35], notably for Be [6.72], Cd [6.69], C, Si, S, Zn and Cr [6.43]. The singly ionized acceptors Be, Zn and Cd (which occupy Ga sites) and the singly ionized donors C and S (which occupy As sites) all diffuse via the kick-out mechanism. The native interstitials involved are Ga_i²⁺ and As_i⁰, apart from Be where the data are best accounted for in terms of the singly ionized interstitial Ga_i¹⁺. Si is an amphoteric dopant and at low concentrations it predominantly occupies Ga sites as a singly ionized donor Si_{Ga}¹⁺. At high concentrations compensation starts to occur due to increasing occupancy as a singly ionized acceptor on As sites. At low

concentrations $\text{Si}_{\text{Ga}}^{1+}$ diffusion is attributed to a vacancy mechanism ($\text{V}_{\text{Ga}}^{3-}$). Cr sits on Ga sites and is a deep-level acceptor dopant important in the growth of high resistivity GaAs. Depending on circumstances, it can diffuse by either the kick-out or the Frank–Turnbull mechanism. The creation of extended defects in the diffusion zone by Zn in-diffusion in GaAs is a well-established feature. The same feature has also been found by *Pöpping* et al. [6.73] for Zn in-diffusion in GaP. They further concluded that Zn diffuses via the kick-out process in GaP through the involvement of either Ga_i^{1+} or Ga_i^{2+} .

6.8.3 Compositional Interdiffusion

The III–V binaries, ternaries and quaternaries are the bases for the fabrication of numerous quantum well and superlattice structures. CID is clearly an issue in the integrity of such structures. The general situation in which the cation and anion sublattices in each layer can contain up to four different components with concentrations ranging from 0 to 100% presents an impossibly complex problem for characterizing diffusion behavior with any rigour. The role of strain in the layers must also be considered a parameter. As a consequence, CID studies have been limited to simpler structures, primarily GaAs–AlAs and GaAs–AlGaAs with interpretations in terms of known diffusion features in GaAs [6.43]. Doping is an important ingredient of these multilayer structures and it was soon discovered that the acceptors Be, C, Mg, Zn and the donors Si, Sn, S, Se and Te could all cause complete disorder of the structure through enhancement of the CID process on either or both sublattices [6.43, 74]. An interesting exception,

however, is found in GaAs–GaAsSb, where either Si or Be reduce CID. Two generally accepted reasons for these dopant effects are: (i) the Fermi-level effect in which the dopant (acceptor/donor) concentration is high enough to make the semiconductor extrinsic so that the concentrations of native (donor/acceptor) defects are increased; (ii) if the dopant diffuses by the kick-out mechanism then in-diffusion will generate a local excess of the native self-interstitial. Clearly (i) operates for dopants incorporated during growth or by subsequent in-diffusion, whereas (ii) is restricted to in-diffusion. Either way the increase in the local native defect concentration(s) leads to a direct enhancement of CID. In the case of GaAs–GaAsSb, cited above, Si will also decrease the concentrations of native donors such as native anion vacancies, which would have a direct impact on and reduction of CID on the anion sublattice. On the other hand, Be should increase native donor concentrations and therefore give enhanced CID of the anions, contrary to observation. Overall, the general features of the dopant-induced disordering process seem to be understood but problems still remain. *Harrison* [6.74] has commented on the approximations commonly made when extracting quantitative information from CID data. The demands of III–V device technology present increasing complexity when attempting to understand the physical processes involved, so that recourse to empirical recipes is sometimes needed. This is illustrated by structures comprising GaInNAs quantum wells with GaAs barriers, all enclosed within AlAs outer layers, whose optoelectronic properties can be improved by the judicious choice of time/temperature anneals [6.75].

6.9 Diffusion in II–VI Compounds

Interest in II–VI materials pre-dates that in the III–Vs because of their luminescence properties in the visible spectrum, which, based on powder technology, resulted in the application of the bigger bandgap materials (such as ZnS) as phosphors in luminescent screens. The development of crystal growth techniques extended interest in the optoelectronic properties of the wider family of II–VI binary compounds formed between the group II cations Zn, Cd and Hg and the group VI anions S, Se and Te. As with the III–Vs, ternary and quaternary compounds are readily formed. The ternary range of compositions $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ has proved to be the most important family member because of their unique properties and consequent extensive exploitation in infra-red systems. ZnS,

CdS and CdSe crystallize in the wurtzite structure, whereas the remaining binaries have the zinc blende structure. The native point defects that can occur are similar to the III–Vs; namely, vacancies, self-interstitials and anti-sites for the cation and anion sublattices. Recent interest has expanded to include the cations Be, Mg and Mn, usually in ternary or quaternary systems. A distinctive feature of atomic diffusion in the II–VI compounds is the much higher diffusivities relative to those in the Group IV and III–V semiconductors. The relative ease of measurement has ensured that much more self- and dopant diffusion data are available compared to the III–Vs. A further difference is that both cation and anion equilibrium vapor pressures are signif-

icant compared to the III–Vs, where the cation vapor pressures are negligible. Unless otherwise stated, the material in the following sections is drawn from the reviews by Shaw [6.6,76,77] and by Capper et al. [6.78].

6.9.1 Self-Diffusion

Where the anion self-diffusivity D_A has been measured as a function of the ambient anion or cation partial pressure in undoped material (ZnSe, CdS, CdSe, CdTe and $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$), a consistent pattern of behavior has emerged: in traversing the composition range from anion-rich to cation-rich, D_A is inversely proportional to the rising cation vapor pressure, P_C , until close to cation saturation, when D_A starts to increase with P_C . Strong donor doping in anion-rich CdS and CdSe had no effect on D_A . This evidence points to either a neutral anion interstitial or a neutral anion anti-site/anion vacancy complex as the diffusion mechanism over most of the composition range, changing to an anion vacancy mechanism as the cation-rich limit is approached.

The situation for cation self-diffusion proves to be more complicated due to the different variations of the cation self-diffusivity D_C with P_C across the compounds. In undoped ZnSe, ZnTe, CdTe and $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$ (above $\approx 300^\circ\text{C}$), D_C is largely independent of P_C across the composition range. Such an independence excludes native point defect diffusion mechanisms and (excluding nondefect mechanisms) points to self-diffusion via neutral complexes such as a cation interstitial/cation vacancy or a cation vacancy/anion vacancy pair. Donor or acceptor doping increases D_C , indicating the involvement of ionized native defects or complexes. The Arrhenius parameters for Zn self-diffusion in undoped ZnSe above 760°C are $D_0 = 9.8\text{ cm}^2/\text{s}$ $Q = 3.0\text{ eV}$ and those for Hg in undoped $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$ above 250°C are $D_0 = 3.8 \times 10^{-3}\text{ cm}^2/\text{s}$ and $Q = 1.22\text{ eV}$. In the case of undoped ZnS, CdS, CdSe and HgTe, D_C generally varies with P_C across the composition range. The simplest variations are found in CdSe and HgTe. In CdSe, D_C can be attributed to the parallel diffusion of singly (1+) and doubly (2+) ionized Cd self-interstitials. D_C in HgTe initially falls with P_C and then increases when crossing from anion-rich to cation-rich material, corresponding to diffusion by a singly ionized (1–) Hg vacancy and by a singly ionized (1+) Hg interstitial respectively. The behavior patterns in ZnS and CdS, however, present substantial problems in their interpretation: donor doping can also enhance D_C , point-

ing to the participation of an ionized native acceptor mechanism.

6.9.2 Chemical Self-Diffusion

Changes in the electrical conductivity or conductivity type caused by step changes to P_C in sample anneals have been used to characterize the change in level of nonstoichiometry through the chemical self-diffusivity, D_Δ , in CdS, CdTe and $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$. D_Δ obviously describes the diffusion of one or more ionized native defects, but in itself it does not identify the defect(s). In CdS and CdTe, D_Δ is attributed to the singly ionized (1+) and/or doubly ionized (2+) Cd interstitial; in CdTe, depending on the temperature, D_Δ exceeds D_C by a factor 10^5 to 10^6 . Modeling based on the simultaneous in-diffusion and out-diffusion of doubly ionized cation interstitials (2+) and vacancies (2–) gives a satisfactory quantitative account of type conversion ($p \rightarrow n$) in $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$ [6.7].

6.9.3 Dopant Diffusion

Although much information on dopant diffusion is available, it is mainly empirical and it is not uncommon for a dopant diffusivity to be independent of dopant concentration (as revealed by an *erfc* profile – a constant diffusivity for a given diffusion profile) under one set of conditions only to give profiles which cannot be characterized by single diffusivities when the conditions are changed. Equally, the variation of a dopant diffusivity with P_C may differ at different temperatures. A further difficulty when attempting to identify a diffusion mechanism is that the local electroneutrality condition is usually not known with any certainty due to significant concentrations of various ionized native defects. A good illustration of the problems encountered is provided by In diffusion in $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$, where diffusion of the singly ionized (1–) pair $\text{In}_{\text{Hg}}\text{V}_{\text{Hg}}$ can account for some of the diffusion features. Some dopants, however, can present clear-cut diffusion properties which permit a well-defined interpretation. The diffusion of As in $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$ is one such case [6.79]. All of the observed features of $D(\text{As})$ are accounted for on the basis that: (i) As occupies both cation and anion lattice sites as singly ionized donors (1+) and acceptors (1–) respectively; (ii) only the ionized donor is mobile and diffuses by a vacancy mechanism on the cation sublattice; (iii) the diffusion sample is electrically intrinsic throughout, so the As concentration is always less than the intrinsic free carrier concentration.

6.9.4 Compositional Interdiffusion

Empirical information, based on bulk material, exists for CID in the following ternaries: (ZnCdHg)Te, (ZnCd)Se, (ZnCdHg)SeTe, (ZnCd)SSe, CdSeTe, ZnCdS, HgCdTe and CdMnTe. It might be expected that features evident in the binaries, such as donor doping enhancing the cation diffusivity but having no effect on that of the anion, and the anion diffusivity increasing (decreasing) with anion (cation) vapor pressure across most of the composition range, would continue to be seen. This means that in a ternary or quaternary system,

donor doping will enhance CID on the cation sublattice, but not on the anion sublattice, and annealing under a high (low) anion (cation) vapor pressure will enhance CID on the anion sublattice. This effect of the anion vapor pressure has been confirmed in CdSSe and CdSeTe and more recently in ZnSSe/ZnSe superlattices [6.80]. In (donor) doping has also been found to enhance the CID of the cations in CdMnTe [6.81], as has N (acceptor) doping in ZnMgSSe/ZnSSe superlattices [6.82]. The consequences of doping on CID in the II–VIs are obviously very similar to the III–V situation.

6.10 Conclusions

The first step in a diffusion investigation is to collect empirical data, which then leads to the second step where experiments can be designed to study the effects of the Fermi level (through the background doping level), of the ambient atmosphere (such as oxidizing, inert or vapor pressure of a system component) and of the sample structure (such as an MBE layer or a quantum well). The third step is to identify the diffusion mechanism and the associated defects using the experimental results in conjunction with the results from first-principles calculations of defect formation energies and their activation energies for diffusion. Clarification of the active processes involved can be gained

by numerical modeling (see Noda [6.83]). These data then provide the basis for the development of process simulators and defect engineering in which the concentrations and spatial distributions of host atoms, dopants and defects are organized according to requirement. Most progress towards achieving this ideal scenario has been made in Si and to a lesser extent in GaAs and $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$. The reality elsewhere is that the boundaries between the steps are blurred, with the third step often being undertaken with inadequate experimental information. Much work remains to be done in order to master our understanding of diffusion processes in semiconductors.

6.11 General Reading and References

General background material for diffusion in semiconductors can be found in Shaw [6.5], Tuck [6.1], Abdullaev and Dzhaferov [6.11] and Tan et al. [6.8]. More specific accounts are given by Fair [6.9] and Fahey et al. [6.84] for Si, by Frank et al. [6.3] for Si and Ge, by Tan and Gösele [6.43] for Si, Ge and GaAs, by Tuck [6.35] for the III–Vs and by Shaw [6.6, 77] for the II–VIs. *H in Semiconductors II* (1999) ed. by N. H. Nickel (*Semi-*

conductors and Semimetals, 61, Academic, San Diego) provides a recent account of H in semiconductors. The volumes in the EMIS Datareviews Series (IEE, Stevenage, UK) cover all of the important semiconductors. The series *Defects and Diffusion in Semiconductors* ed. by D. J. Fisher (Trans Tech., Brandrain 6, Switzerland) offers an annual and selective retrospective of recent literature.

7. Photoconductivity in Materials Research

Photoconductivity is the incremental change in the electrical conductivity of a substance upon illumination. Photoconductivity is especially apparent for semiconductors and insulators, which have low conductivity in the dark. Significant information can be derived on the distribution of electronic states in the material and on carrier generation and recombination processes from the dependence of the photoconductivity on factors such as the exciting photon energy, the intensity of the illumination or the ambient temperature. These results can in turn be used to investigate optical absorption coefficients or concentrations and distributions of defects in the material. Methods involving either steady state currents under constant illumination or transient methods involving pulsed excitation can be used to study the electronic density of states as well as the recombination. The transient time-of-flight technique also allows carrier drift mobilities to be determined.

Photoconductivity has traditionally played a significant role in materials research, and most notably so in the study of covalently bonded semiconductors and insulators. Indeed, since it is the incremental conductivity generated by the absorption of (optical) photons, photoconductivity can be most clearly resolved in situations where the intrinsic dark conductivity of the material is low. This conductivity in the dark, leading to “dark current”, is due to the thermal equilibrium density of free carriers in the material and must be subtracted from any measured current in order to obtain the actual photocurrent. The basic processes that govern the magnitude of the photocurrent are the generation of free electrons and holes through the absorption of incident photons, the transport of those free carriers through the material under the influence of an electric field, and the recombination of the photoexcited electrons and holes. The study of any of those aspects as a function of the characteristics of the current-inducing illumination, as well as the study of their development upon changes in that illumi-

nation over time, will offer insights into the structure and electronic properties of the material under investigation. However, given the fact that three separate processes are involved in the production of a specific photocurrent, it follows that any analysis of experimental data in terms of system parameters will require a sufficiently comprehensive data set that will allow for differentiation between alternative interpretations. For instance, a low photocurrent may be the result of a low optical absorption coefficient at the given photon energy, but it may also be due to significant geminate recombination of the photogenerated electron-hole pairs, or it may reflect the formation of excitons. The combined use of different types of photoconductivity experiments is therefore often advisable, as is the combination of photoconductivity with related experiments such as photoluminescence or charge collection.

A wide variety of experimental techniques based on photoconductivity have come into general use over the years. They can be divided into two main groups, one

involving steady state photoconductivity (SSPC), where the focus is on stationary photocurrent levels, and a second one involving transient effects (TPC) where the time evolution of the photocurrent is studied. We will use this division in our survey of the various methods, but we should point out that SSPC can also be measured through ac excitation. The information that can be obtained about the material under investigation is generally not specific to either the SSPC or TPC method that is used, but will depend on the wider context of the

measurements. Recombination can be studied via TPC, but the temperature dependence of SSPC can also be used to identify different recombination mechanisms, while details of the electronic density of states (DOS) in the band gap of a semiconductor can be inferred either from the spectral response of the SSPC or from a proper analysis of TPC. Detailed discussions of the general principles of photoconductivity may be found in the standard monographs by Bube [7.1, 2], Ryvkin [7.3] and Rose [7.4].

7.1 Steady State Photoconductivity Methods

7.1.1 The Basic Single-Beam Experiment

The simplest photoconductivity experiment uses a constant monochromatic light source to generate equal excess densities of free electrons and holes, $\Delta n = \Delta p$, that lead to a change in the conductivity by

$$\Delta\sigma = \sigma_{ph} = e(\mu_n \Delta n + \mu_p \Delta p), \quad (7.1)$$

where e is the electronic charge and μ_n and μ_p are the electron and hole mobilities, respectively. The basic experimental arrangement is illustrated in Fig. 7.1a, where L and A are the length and the cross-sectional area of the sample and the photocurrent I_{ph} corresponds to $\sigma_{ph}AF$, where $F = V/L$ is the electric field applied. The end surfaces of the sample are covered by a metallic electrode. However, since materials of current interest are often used in thin film rather than bulk form, interdigitated electrodes of the type shown in Fig. 7.1b are frequently used in actual measurement geometries. In general, a fraction of the photogenerated carriers becomes immobilized by getting trapped at various defects such that not every part of Δn and Δp contributes equally to the photoconductivity in (7.1). The effect of such trapping on the photoconductivity is reflected in the use of values for the mobilities μ_n and μ_p that are lower – and not necessarily symmetrically lower – than the theoretical free-carrier mobility μ_0 . In fact, for

a significant number of materials with widespread practical applications, one of either the product $\mu_n \Delta n$ or the product $\mu_p \Delta p$ turns out to be much larger than the other because of strongly unequal carrier mobilities. For instance, the electron term dominates in intrinsic silicon,

Fig. 7.1 (a) Basic arrangement for photoconductivity measurements, with V the applied voltage, L the sample length and A the cross-sectional area. I_d , n_0 and p_0 are the current and the carrier densities in the dark, and I_{ph} , Δn , Δp are the incremental values caused by the illumination. (b) Example of interdigitated electrode configuration for a thin film sample. (c) Schematic time development of the excess carrier concentration Δn in response to a period of illumination

while the photocurrent in chalcogenide glasses is carried by holes. In those instances, (7.1) effectively reduces to a one-carrier equation.

In the $\mu_n \Delta n$ or $\mu_p \Delta p$ products, the mobility μ_i is a material parameter that, in general, will depend on temperature and sample characteristics, while the excess carrier density $\Delta n = \Delta p$ is determined by a combination of material and external parameters. Phenomenologically, the excess density Δn can be written as the product $G\tau_i$, where G is the rate of generation of free electrons and holes per unit volume, and τ_i is the average lifetime of the excess carrier. Introducing these quantities into (7.1) leads to the form

$$\sigma_{ph} = eG(\mu_n \tau_n + \mu_p \tau_p), \quad (7.2)$$

which explicitly displays the mobility–lifetime products that are frequently used to characterize photoconductors. The relationship between the steady state values of Δn and G is illustrated in Fig. 7.1c, where the build-up and decay of Δn when the illumination is turned on and turned off are also shown. Those time-dependent aspects of photoconductivity will be addressed in a later section.

The generation rate G is defined by

$$G = \eta(I_0/h\nu)(1 - R)[1 - \exp(-\alpha d)]/d, \quad (7.3)$$

where η is the quantum efficiency of the generation process, I_0 is the incident illumination intensity (energy per unit time and unit area), $h\nu$ is the photon energy, R is the reflection coefficient of the sample, α is the optical absorption coefficient of the material, and d is the sample thickness. A quantum efficiency $\eta < 1$ signifies that, due to geminate recombination of the carriers or of exciton formation, not every absorbed photon generates a free electron and hole that will contribute to the photocurrent. The values of the parameters η , R and α depend, in general, on the wavelength of the illuminating light. Consequently, monochromatic illumination from a tunable light source can be used to obtain energy-resolved information about the sample, while illumination with white light will only offer a global average. Under many experimental circumstances, the condition $\alpha d \ll 1$ will hold over a significant energy range (when the sample thickness is small with respect to the optical absorption depth of the material). Equation (7.3) can then be simplified to

$$G \cong \eta(I_0/h\nu)(1 - R)\alpha. \quad (7.4)$$

The free-carrier lifetimes of the excess electrons and holes, τ_n and τ_p , in (7.2) are governed by recombination with carriers of opposite sign. Assuming, for

simplicity, the frequently encountered case of photoconductivity dominated by one type of carrier (known as the majority carrier), and assuming electrons to be the majority carrier, the recombination rate can be written as $\tau_n^{-1} = b(p_0 + \Delta p)$, where b is a recombination constant, and p_0 and Δp are the equilibrium and excess minority carrier densities. It then follows that the photoconductivity

$$\begin{aligned} \sigma_{ph} \propto \Delta n &= G\tau_n = G/b(p_0 + \Delta p) \\ &= G/b(p_0 + \Delta n). \end{aligned} \quad (7.5)$$

Equation (7.5) indicates that a linear relationship $\sigma_{ph} \propto G$ holds for $\Delta n \ll p_0$ (a low excess carrier density), while high excitation levels with $\Delta n \gg p_0$ lead to $\sigma_{ph} \propto G^{1/2}$. These linear and quadratic recombination regimes are also referred to as mono- and bimolecular recombination. For a given light source and temperature, variations in G correspond to variations in the light intensity I_0 , and therefore $\sigma_{ph} \propto I_0^\gamma$ with $1/2 \leq \gamma \leq 1$. The value of γ itself will of course depend on the light intensity I_0 . However, I_0 is not the only factor that determines the value of γ : intermediate γ values may indicate a $\Delta n \approx p_0$ condition, but they may equally be caused by a distribution of recombination centers, as outlined below [7.4].

From a materials characterization point of view, SSPC offers the possibility of using the above equations to determine the absorption coefficient as a function of the energy of the incoming photons, and thus explore the electronic density of states around the band gap of a semiconductor. When single-crystalline samples of materials with sufficiently well-defined energy levels are studied, maxima corresponding to specific optical transitions may be seen in the photoconductivity spectra. A recent example, involving the split valence band of a p-CdIn₂Te₄ crystal, may be found in You et al. [7.5]. Another example is given in Fig. 7.2, where the spectral distribution of the photocurrent is shown for optical-quality diamond films prepared by chemical vapor deposition [7.6]. The rise in photocurrent around 5.5 eV corresponds to the optical gap of diamond, while the shoulders at ≈ 1.5 eV and ≈ 3.5 eV signal the presence of defect distributions in the gap. The data in Fig. 7.2 were obtained under ac conditions using chopped light and a lock-in amplifier. The changes in the observed phase shift can then also be used to locate the energies at which transitions to specific features of the density of states (DOS) become of importance. The use of ac excitation and lock-in detection has the added advantage of strongly reducing uncorrelated noise, but

care must be taken to ensure that the ac frequency remains lower than the response rate of the investigated system over the spectral range of interest.

The equilibrium free-carrier densities n_0 and p_0 , which play a role in the recombination pro-

Fig. 7.2 Room temperature ac photocurrent spectra, measured at 7 Hz, after various treatments of CVD diamond layers deposited at 920 °C (S2) and 820 °C (S3) (after [7.6])

cess, depend on the temperature through the approximate Fermi–Dirac occupation probability function $\exp[(E - E_F)/kT]$, thus making recombination a temperature-dependent process. In photoconductors, recombination is mediated by carrier traps in the bandgap. The presence of discrete trapping levels leads to thermally activated photocurrents, with the activation energy indicating the energetic positions of the traps. *Main and Owen* [7.8] and *Simmons and Taylor* [7.9] showed that the positive photocurrent activation energy in the monomolecular recombination regime corresponds to the distance above the Fermi level of a donor-like center, while a negative activation energy value in the bimolecular region refers to the energy position above the valence band edge of an acceptor-like center. Figure 7.3 illustrates this photocurrent behavior for amorphous As_2Se_3 [7.7]. The above pattern is characteristic of chalcogenide glasses, where the intrinsic charged defects with negative effective correlation energy act as recombination centers [7.10]. *SSPC* measurements can thus determine the recombination levels of those defects.

In highly photosensitive materials, such as selenium or hydrogenated amorphous silicon (a-Si:H), measurements in the monomolecular region are hindered by the problem of satisfying the $\Delta n \ll p_0$ condition. In addition, the *SSPC* temperature dependence in a-Si:H does not exhibit a definite activation energy due to the presence of a more distributed and complex set of traps that even induce regions of superlinear dependence on light intensity [7.11]. This illustrates that *SSPC* analysis is not necessarily straightforward.

Whenever the electronic density of states in the band gap of a photoconductor consists of a distribution of traps (as is the case in amorphous materials), a quasi-Fermi level $E_{qF} = E_F - kT \ln(1 + \Delta n/n)$, linked to the excess carrier density, can be defined. This quasi-Fermi level will – to a first approximation – correspond to the de-

Fig. 7.3a,b Temperature dependence of the steady state dark and photocurrents in an a- As_2Se_3 bulk sample, illuminated at 1.55 eV with intensities of 0.84, 3.5, 9.8, 38 and 120×10^{12} photons/cm²s (a), and illuminated at 1.85 eV with intensities of 0.56, 1.7, 4.6, 27 and 77×10^{12} photons/cm²s (b). ΔE_m and ΔE_b represent the photocurrent activation energies in the monomolecular and bimolecular recombination regimes respectively, and E_σ is the activation energy of the dark current I_d (after [7.7])

marcation level that divides the DOS into a shallower part where carriers will be trapped and subsequently re-emitted and a deeper part where traps have become recombination centers. In other words, varying the light intensity influences both carrier generation and recombination rates. When several trapping centers with quite different characteristics are present in the photoconductor, shifts in the positions of the quasi-Fermi levels can then produce unexpected results. Instances of $\sigma_{ph} \propto I_0^\gamma$, with $\gamma > 1$ (as referred to above) will be observed for some materials, while combinations that actually produce *negative* photoconductivity, $\sigma_{ph} < 0$, have also been encountered [7.4].

7.1.2 The Constant Photocurrent Method (CPM)

The constant photocurrent method (CPM) has been used by Vaněček and coworkers [7.12, 13] to determine the optical absorption coefficient as a function of photon energy, $\alpha(E)$, via (7.2–7.4). In CPM, the photocurrent is kept constant by continually adjusting the light intensity I_0 while the photon energy is scanned across the spectrum. The constant photocurrent implies that the quasi-Fermi levels have immobile positions and thus that the free-carrier lifetime is a constant, τ . It then follows that in

$$\sigma_{ph} = e\mu\tau(I_0/h\nu)(1 - R)\eta\alpha \quad (7.6)$$

the product $(I_0/h\nu)\alpha$ will remain constant, and that α can be determined from it, provided that any energy dependencies for the parameters μ , R and η of (7.6) are negligible. The value at which the photocurrent is fixed can be chosen freely, but will in practice be dictated by the low-absorption region of the sample. However, since even low-level photocurrents can still be measured with high precision, the method is especially useful at low values of optical absorption where standard transmission measurements lose their accuracy.

In ‘absolute’ CPM, the optical transmission through the film is measured at the same time as the photocurrent, and the data from the two measurements are combined in order to remove optical interference fringes from the data and to fix the value of the proportionality constant [7.12]. The experimental arrangement used in such absolute CPM measurements is shown schematically in Fig. 7.4. The CPM experiment can be operated with either dc or ac illumination, but the absorption spectra retrieved will not be identical. AC illumination can be obtained using a mechanical chopper (as suggested in Fig. 7.4), but also, for instance, from an ac-driven light-emitting

Fig. 7.4 Schematic diagram of an ‘absolute’ CPM set-up. Photodetector D1 is used to regulate the intensity of the lamp, while detector D2 measures the transmitted light (after [7.12])

diode. Main et al. [7.14] showed that, in the dc mode, transitions involving initially unoccupied DOS levels raise the absorption above the value that is seen with the ac technique. Systematic comparison of *dc* and *ac* results allows us, therefore, to distinguish between occupied states below the operative Fermi level and unoccupied ones above it. In cases where the quantum efficiency of carrier generation η can be taken as unity, CPM gives $\alpha(E)$ directly as $1/I_0$, and this method is widely used, for example for hydrogenated amorphous silicon. However, for materials such as chalcogenide glasses or organic semiconductors where η itself is energy-dependent, it is only the product $\eta\alpha$ that is readily obtained.

7.1.3 Dual-Beam Photoconductivity (DBP)

Like the CPM discussed above, the dual-beam photoconductivity (DBP) technique is used to determine the sub-bandgap optical absorption in a photoconductor. A constant, uniformly absorbed illumination I_0 is used to establish a constant excess carrier density in the material, and hence a constant free-carrier lifetime τ . The chopped signal $I'(E)$ of a low-intensity, tunable light source is added to this background to generate variations in photoconductivity $\delta\sigma_{ph}(E)$. Synchronous lock-in detection of the small ac signal then provides the information needed to deduce $\alpha(E)$. By carrying out measurements at different values of the background illumination intensity, DBP allows the photoconductor absorption to be tested for changing quasi-Fermi level positions. Changes in the resolved $\alpha(E)$ curves can then be used to obtain information on the DOS distribution in the sample. An example of this use of DBP can be found in Günes et al. [7.15], where differences in absorption between annealed and light-soaked hydrogenated amorphous silicon samples are studied.

7.1.4 Modulated Photoconductivity (MPC)

The experimental technique that has become known as modulated photoconductivity (MPC) is used to determine the energetic distribution of states in the bandgap of a photoconductor by analyzing the phase shift between ac photoexcitation and the ensuing ac photocurrent as a function of the modulation frequency of the light [7.17, 18]. Figure 7.5 shows the essential parts of an MPC set-up, and illustrates the phase difference between the illumination and the photocurrent. Two modulation frequency ranges with distinct characteristics are identified. In the high-frequency region, from a few Hz up to the kHz range, the signal is dominated by carrier release from traps, with a release rate that matches the modulation frequency. The usual assumption, that the release probability decreases exponentially with the trap depth according to $r \propto \exp(-E/kT)$, gives the link between the measured phase shift and the DOS of the material. The relationship between the two is expressed by

$$g(E) \propto \sin(\Phi)/I_{ac}, E = k_B T \ln(v_0/\omega), \quad (7.7)$$

Fig. 7.5 Schematic diagram of an MPC set-up (upper frames), and of the phase relationship between the exciting light intensity and the resulting photocurrent (lower frames)

where Φ and I_{ac} are the phase and intensity of the ac photocurrent, k_B is the Boltzmann constant, T the temperature, v_0 the attempt-to-escape frequency and ω the modulation frequency. At the low-frequency end, recombination and trapping in deep states determine the phase shifts and the DOS varies according to $\tan(\Phi)/\omega$. The transition between the two regions is tied to the position of the quasi-Fermi levels and can, therefore, be shifted by changing the illumination intensity. MPC works best with photoconductors where one carrier type dominates the current, and therefore only one side of the bandgap needs be taken into account in the analysis. Examples of MPC-determined DOS profiles are given in Fig. 7.6 [7.16]. The figure shows a profile for the conduction band side of the bandgap of an as-deposited polymorphous silicon sample, as well as those for the sample following light soaking and after subsequent annealing.

Fig. 7.6 DOS below the CB edge of a polymorphous silicon sample deposited at 423 K and measured (by MPC) as-deposited, after light soaking, and after two stages of subsequent annealing (after [7.16])

7.2 Transient Photoconductivity Experiments

The study of transient aspects of photoconductivity can relate to either the build-up or the relaxation of steady state photocurrents, or to a material's response to pulsed excitation. While the SSPC turn-on transient reflects the interplay between generation and recombination of carriers (an interplay that often leads to a current overshoot at high excitation levels), the SSPC relaxation upon turn-off only involves recombination and is therefore

easier to analyze. Nevertheless, a simple exponential decay of the photocurrent, as sketched in Fig. 7.1c, will only be observed when a unique recombination path is followed, a situation that is the exception rather than the rule. Transient photoconductivity (TPC) caused by pulsed excitation is generally simpler to analyze. Indeed, whereas a quasi-equilibrium distribution of trapped photogenerated carriers will build up or be present in the

photoconductor's bandgap under **SSPC**, the **TPC** experiments can be analyzed against the background of the thermal equilibrium distribution of carriers in the material.

7.2.1 Current Relaxation from the Steady State

Upon termination of steady state illumination, the generation term drops out of the rate equation that describes the nonequilibrium carrier distribution, but the carrier density itself and the operative recombination process are not altered. Consequently, the initial photocurrent decay will be governed by whatever recombination mode existed under **SSPC** conditions. Spectroscopic analysis of the relaxation current in terms of the distribution of states in the bandgap can be readily achieved in the case of monomolecular recombination [7.19], with the product of photocurrent and time being proportional to the **DOS**:

$$I_{\text{ph}}(t)t \propto g(E), \quad E = k_B T \ln(v_0 t). \quad (7.8)$$

In (7.8), $k_B T$ is the Boltzmann energy and v_0 is the attempt-to-escape frequency. When, on the other hand, bimolecular recombination dominates, the link between the current and the distribution of recombination centers is much less direct and spectroscopic analysis is difficult. Unfortunately, bimolecular recombination is dominant in good photoconductors.

In spite of the above, relaxation of the steady state current has often been used to obtain a first-order estimate for free-carrier lifetimes, even when this had to be done on a purely phenomenological basis due to a lack of sufficient information on the recombination mechanisms involved. An exponential fit to the initial part of the decay is then often used to make the estimate. In cases where more than one – sometimes vastly different – recombination mechanisms are operative, this initial decay does not necessarily represent the most significant proportion of carriers. This is certainly the case whenever so-called persistent photoconductivity is observed; one of the relaxation times involved is then longer than the observation time.

7.2.2 Transient Photoconductivity (TPC)

In the standard transient photoconductivity (**TPC**) experiment, free carriers are excited into the transport band at time $t = 0$ by a short light pulse. They are then moved along by the electric field until their eventual disappearance through recombination, but before this happens

they will have been immobilized a number of times by various traps that are present in the material. Since the carrier distributions are in thermal equilibrium at the start of the experiment, both the trapping sites for electrons above the Fermi level and the hole trapping sites below E_F are empty, such that the newly created carriers are not excluded from any of those trapping sites. Given that carrier release from a trap is a thermally activated process with the trap depth being the activation energy, deeper traps immobilize carriers for longer times and lead to lower values for the transient current. As shallower states release trapped carriers sooner, retrapping of those carriers will lead to increased occupation of the deeper states and further reduction of the current level. To allow this thermalization of the excited carriers to run its full course until recombination sets in, the experiments are traditionally carried out in the so-called secondary photocurrent mode, whereby the sample is supplied with ohmic electrical contacts and carrier loss is by recombination only. Coplanar electrode geometries (gap cells) are mostly used. Expressions that link the transient current to the distribution of localized states can be derived [7.20], but they are difficult to invert in the general case. Nevertheless, as long as recombination can be neglected, the relationship $g(E) \propto [I(t)t]^{-1}$ can be used as a first-order estimate.

For the special case of an exponential **DOS**, the solution is straightforward: a $g(E) \propto \exp(-E/E_0)$ distribution of trapping levels leads to a power law for the transient current $I(t) \propto t^{-(1-\alpha)}$ with $\alpha = k_B T/E_0$. In other words, the width of the exponential distribution E_0 can be deduced from the slope of the power law decay of the current. Essentially exponential distributions were found to dominate the valence band tail of equilibrated amorphous As_2Se_3 samples over a wide energy range [7.7], but no other examples have emerged.

An elegant way to circumvent the difficulties posed by a time domain analysis of the transient current is to transpose the current decay into the frequency domain by a Fourier transform [7.21]. Since the **TPC** current decay is the photoconductor's response to an impulse excitation, its Fourier transform gives the frequency response $I(\omega)$ of that photoconductor. In fact, this $I(\omega)$ corresponds to the photocurrent intensity I_{ac} as used in the **MPC** method, and the same procedures can thus be used to extract the information on density and energy distribution of localized states in the band gap. Not just Fourier transform but also Laplace transform techniques have been applied to the conversion of **TPC** signals into **DOS** information. A comparison and discussion of the results may be found in [7.22]. Examples of Fourier

Fig. 7.7 DOS below the conduction band edge in a-Si:H, obtained through Fourier transforms of the transient photocurrent; HFT: the high-resolution analysis of [7.22], FT: the earlier analysis according to [7.21]

transform TPC analysis, as originally proposed and as developed since, are shown in Fig. 7.7 for an a-Si:H sample. Whereas the energy range that can be probed is limited in MPC by the frequency range of the lock-in amplifier, it is the smallest resolution time of the detection system that limits the range in the case of TPC, the latter one being generally more advantageous.

7.2.3 Time-of-Flight Measurements (TOF)

The time-of-flight (TOF) experiment, originally designed to determine the drift mobility of free carriers in high-mobility materials, has been highly successfully adapted to low-mobility materials such as organic or amorphous semiconductors [7.24], where it has been used for drift mobility measurements but also as an alternative TPC technique to study the energy distribution of localized states. While majority carriers will dominate photocurrents in traditional TPC, TOF allows independent measurements with majority and minority carriers, and thus independent examinations of the valence band side and conduction band side of the band gap.

For TOF measurements, the sample consists of a layer of the photoconducting material sandwiched between two electrodes that are blocking carrier injection into the sample. At least one of the electrodes must be semitransparent to permit the photoexcitation of free carriers in the material just beyond the illuminated contact by a strongly absorbed light flash. Depending on the polarity of the electric field applied across the sample, either electrons or holes will then be drifted through the sample. At their arrival at the back contact, the current will drop since the blocking contact ensures that only the primary photocurrent is measured. From the transit time

Fig. 7.8 TOF measurement set-up shown for the case of holes being drifted through the length L of the sample by a positive applied voltage. Choosing the resistance R that generates an output voltage to be low minimizes RC distortion of the signal at short times; choosing it to be high enhances the detectability of weak signals at the expense of time resolution

t_T (the time needed for the charge sheet to cross the sample), the drift mobility μ_d can be calculated according to $\mu_d = L/t_T F$, where L is the sample length and F the applied electric field. The essential elements of a TOF

Fig. 7.9 Time-of-flight transients measured at 243 K in methyl-substituted ladder-type poly(para)phenylene (MeLPPP) with 60 kV/cm (line) and 300 kV/cm (●) applied, and normalized to a transit time set to 90% of the pre-transit current. The inset shows the chemical structure of MeLPPP (after [7.23])

Fig. 7.10 Example of TOF hole transients measured at several temperatures, as indicated, with 10 V applied across a 5.6 μm -thick a-Si:H sample grown in an expanding thermal plasma at 0.85 nm/s and 250 $^{\circ}\text{C}$ substrate temperature, and sandwiched between Mo contacts (after [7.25])

measuring circuit are displayed in Fig. 7.8. The transit time can be measured directly on the current trace, in which case it is variously defined as the time at which the current has dropped by values ranging from 10% to 50% (the latter one being most commonly used), or it can be obtained by integrating the current and using the time at which the collected charge saturates. Obtaining a true value of μ_d requires that the field F be uniform and constant during the carrier transit, which means that F should only be applied a short time before the optical excitation and that the transit time should be short with respect to the dielectric relaxation time in the material. Figure 7.9 shows TOF transients in a conjugated polymer whereby a 10% drop is used to define the transit time.

In materials with a wide distribution of localized gap states, as is generally the case in disordered photoconductors, the drifting charge package spreads out along the length of the sample, and a representative transit time can only be discerned as a change of slope in a double-logarithmic plot of current versus time. The curves in Fig. 7.10 (from [7.25]) illustrate such behavior. Measurements at different temperatures and applied fields are then needed to ascertain that the observed feature marks an actual carrier transit rather than deep trapping of the photogenerated charge. In the materials that exhibit this anomalously dispersive transport, the pre-transit current will have the characteristics of the TPC described in the previous section,

and the information about the distribution of gap states $g(E)$ that is contained in the current transient can be extracted in the same ways. Both pre-transit current transients and measured drift mobility values have been employed in the past to estimate the DOS in the band tails of disordered semiconductors. In the latter case, specific $g(E)$ functions are explored through trap-controlled transport modeling to reproduce the experimental dependence of μ_d on the temperature and the electric field. This technique has since been replaced by the more direct procedures described in preceding sections.

At times longer than the TOF transit time, a steeper current decay testifies to the fact that carriers are leaving the sample. The post-transit current that is then observed is increasingly due to the emission of carriers that were trapped in states deep in the bandgap. Provided that the conditions are such that the probability of subsequent deep retrapping of the same carriers is negligible, a proper analysis of these post-transit TOF current transients permits the elucidation of the distribution of localized states deeper in the gap [7.27] with, as in (7.8), $g(E) \propto I(t)t$ expressing the correspondence.

7.2.4 Interrupted Field Time-of-Flight (IFTOF)

The interrupted field time-of-flight (IFTOF) experiment differs from the time-of-flight experiment described

Fig. 7.11a,b Comparison of current traces in TOF (a) and IFTOF (b) experiments. The applied electric field is turned off in case (b) for a length of time t_1 (after [7.26])

in the previous section in that the applied field that drives the photogenerated carrier packet through the sample is turned off for some period of time before the carriers have completed their transit. As illustrated in Fig. 7.11, a lower current intensity is measured when the field is turned on again, signalling that some of the drifting carriers have become immobilized in deep traps [7.28]. By studying the drop in current as a function of the interruption time t_i , the deep-trapping lifetime of the carriers can be evaluated. Recombination can be routinely neglected in TOF experiments since only one type of carrier drifts through the sample, but by charging a sample with carriers of one polarity before performing an IFTOF experiment that drifts carriers of the opposite polarity through

the sample, recombination parameters can be studied too [7.29].

Another interesting method for studying the recombination process is – just like IFTOF – based on a simple modification of the TOF experiment: after generating free carriers through one contact and drifting the slower type of carrier into the sample, a second light pulse through the other contact sends a sheet of oppositely charged carriers towards the first one. The two carrier packages will cross and some electrons and holes will recombine during that crossing, thereby affecting the observed current levels and providing a way to study the recombination process. An elegant example of the application of this technique to amorphous selenium can be found in Haugen and Kasap [7.30].

8. Electronic Properties of Semiconductor Interfaces

In this chapter we investigate the electronic properties of semiconductor interfaces. Semiconductor devices contain metal–semiconductor, insulator–semiconductor, insulator–metal and/or semiconductor–semiconductor interfaces. The electronic properties of these interfaces determine the characteristics of the device. The band structure lineup at all these interfaces is determined by one unifying concept, the continuum of interface-induced gap states (IFIGS). These intrinsic interface states are the wavefunction tails of electron states that overlap the fundamental band gap of a semiconductor at the interface; in other words they are caused by the quantum-mechanical tunneling effect. IFIGS theory quantitatively explains the experimental barrier heights of well-characterized metal–semiconductor or Schottky contacts as well as the valence-band offsets of semiconductor–semiconductor interfaces or

semiconductor heterostructures. Insulators are viewed as semiconductors with wide band gaps.

In his pioneering article entitled *Semiconductor Theory of the Blocking Layer*, Schottky [8.1] finally explained the rectifying properties of metal–semiconductor contacts, which had first been described by Braun [8.2], as being due to a depletion of the majority carriers on the semiconductor side of the interface. This new depletion-layer concept immediately triggered a search for a physical explanation of the barrier heights observed in metal–semiconductor interfaces, or Schottky contacts as they are also called in order to honor Schottky’s many basic contributions to this field.

The early Schottky–Mott rule [8.3,4] proposed that n-type (p-type) barrier heights were equal to the difference between the work function of the metal and the electron affinity (ionization energy) of the semiconductor. A plot of the experimental barrier heights of various metal–selenium rectifiers versus the work functions of the corresponding metals did indeed reveal a linear correlation, but the slope parameter was much smaller than unity [8.4]. To resolve the failure of

the very simple and therefore attractive Schottky–Mott rule, Bardeen [8.5] proposed that electronic interface states in the semiconductor band gap play an essential role in the charge balance at metal–semiconductor interfaces.

Heine [8.6] considered the quantum-mechanical tunneling effect at metal–semiconductor interfaces and noted that *for energies in the semiconductor band gap, the volume states of the metal have tails in the semiconductor*. Tejedor and Flores [8.7] applied this same idea to semiconductor heterostructures where, for energies in the band-edge discontinuities, the volume states of one semiconductor tunnel into the other. The continua of interface-induced gap states (IFIGS), as these evanescent states were later called, are an intrinsic property of semiconductors and they are the *fundamental* physical mechanism that determines the band-structure lineup at both metal–semiconductor contacts and semiconductor heterostructures: in other words, at all semiconductor interfaces. Insulator interfaces are also included in this, since insulators may be described as wide-gap semi-

Fig. 8.1 Schematic energy-band diagrams of metal–semiconductor contacts and semiconductor heterostructures. conductors. Figure 8.1 shows schematic band diagrams of an n-type Schottky contact and a semiconductor heterostructure.

The **IFIGS** continua derive from both the valence- and the conduction-band states of the semiconductor. The energy at which their predominant character changes from valence-band-like to conduction-band-like is called their branch point. The position of the Fermi level relative to this branch point then determines the sign and the amount of the net charge in the **IFIGS**. Hence, the **IFIGS** give rise to intrinsic interface dipoles. Both the barrier heights of Schottky contacts and the band offsets of heterostructures thus divide up into a zero-charge-transfer term and an electric-dipole contribution.

From a more chemical point of view, these interface dipoles may be attributed to the partial ionic character of the covalent bonds between atoms right at the interface. Generalizing *Pauling's* [8.8] electronegativity concept,

the difference in the electronegativities of the atoms involved in the interfacial bonds also describes the charge transfer at semiconductor interfaces. Combining the physical **IFIGS** and the chemical electronegativity concept, the electric-dipole contributions of Schottky barrier heights as well as those of heterostructure band offsets vary proportional to the difference in the electronegativities of the metal and the semiconductor and of the two semiconductors, respectively. The electronegativities of the Group IV elemental and the IV–IV, III–V, and II–VI compound semiconductors are almost equal, since the elements that constitute these semiconductors are all placed in the middle of the Periodic Table. Hence, the **IFIGS** dipole terms of the respective semiconductor heterostructures will be small and may be neglected [8.9]. The valence-band offsets of nonpolar, of lattice-matched and of metamorphic heterostructures should thus equal the difference between the branch-point energies of the semiconductors in contact.

The theoreticians appreciated *Heine's* **IFIGS** concept at once. The initial reluctance of most experimentalists was motivated by the observation that the predictions of the **IFIGS** theory only marked upper limits for the barrier heights observed with *real* Schottky contacts [8.10]. *Schmitsdorf* et al. [8.11] finally resolved this dilemma. They found a linear decrease in the effective barrier height with increasing ideality factors for their Ag/n-Si(111) diodes. Such behavior has been observed for all of the Schottky contacts investigated so far. *Schmitsdorf* et al. attributed this correlation to patches of decreased barrier heights and lateral dimensions smaller than the depletion layer width [8.12]. Consequently, they extrapolated their plots of effective barrier height versus ideality factor to the ideality factor determined by the image-force or Schottky effect [8.13] alone; in this way, they obtained the barrier heights of the laterally homogeneous contacts. The barrier heights of laterally uniform contacts can also be determined from capacitance–voltage measurements (C/V) and by applying ballistic-electron-emission microscopy (**BEEM**) and internal photoemission yield spectroscopy (**IPEYS**). The I/V , C/V , **BEEM**, and **IPEYS** data agree within the margins of experimental error.

Mönch [8.14] found that the barrier heights of laterally homogeneous Schottky contacts as well as the experimentally observed valence band offsets of semiconductor heterostructures agree excellently with the predictions of the **IFIGS**-and-electronegativity theory.

8.1 Experimental Database

8.1.1 Barrier Heights of Laterally Homogeneous Schottky Contacts

I/V Characteristics

The current transport in real Schottky contacts occurs via thermionic emission over the barrier provided the doping level of the semiconductor is not too high [8.15]. For doping levels larger than approximately 10^{18} per cm^3 , the depletion layer becomes so narrow that tunnel or field emission through the depletion layer prevails. The current–voltage characteristics then become ohmic rather than rectifying.

For thermionic emission over the barrier, the current–voltage characteristics may be written as (see, for example, [8.14])

$$I_{\text{te}} = AA_{\text{R}}^* T^2 \exp\left(-\Phi_{\text{Bn}}^{\text{eff}}/k_{\text{B}}T\right) \exp(e_0 V_{\text{c}}/nk_{\text{B}}T) \times [1 - \exp(-e_0 V_{\text{c}}/k_{\text{B}}T)], \quad (8.1)$$

where A is the diode area, A_{R}^* is the effective Richardson constant of the semiconductor, and k_{B} , T , and e_0 are Boltzmann's constant, the temperature, and the electronic charge, respectively. The effective Richardson constant is defined as

$$A_{\text{R}}^* = \frac{4\pi e_0 k_{\text{B}} m_n^*}{h^3} = A_{\text{R}} \frac{m_n^*}{m_0}, \quad (8.2)$$

where $A_{\text{R}} = 120 \text{ A cm}^{-2} \text{ K}^{-2}$ is the Richardson constant for thermionic emission of nearly free electrons into vacuum, h is Planck's constant, and m_0 and m_n^* are the vacuum and the effective conduction-band mass of electrons, respectively. The externally applied bias V_{a} divides up into a voltage drop V_{c} across the depletion layer of the Schottky contact and an IR drop at the series resistance R_{s} of the diode, so that $V_{\text{c}} = V_{\text{a}} - IR_{\text{s}}$. For *ideal* (intimate, abrupt, defect-free, and, above all, laterally homogeneous) Schottky contacts, the effective zero-bias barrier height $\Phi_{\text{Bn}}^{\text{eff}}$ equals the difference $\Phi_{\text{Bn}}^{\text{hom}} - \delta\Phi_{\text{if}}^0$ between the homogeneous barrier height and the zero-bias image-force lowering (see [8.14])

$$\delta\Phi_{\text{if}}^0 = e_0 \left[\frac{2e_0^2 N_{\text{d}}}{(4\pi)^2 \varepsilon_{\infty}^2 \varepsilon_{\text{b}} \varepsilon_0^3} \left(e_0 |V_{\text{i}}^0| - k_{\text{B}}T \right) \right]^{1/4}, \quad (8.3)$$

where N_{d} is the donor density, $e_0 |V_{\text{i}}^0|$ is the zero-bias band bending, ε_{∞} and ε_{b} are the optical and the bulk dielectric constant, respectively, and ε_0 is the permittivity

of vacuum. The ideality factor n describes the voltage dependence of the barrier height and is defined by

$$1 - 1/n = \partial\Phi_{\text{Bn}}^{\text{eff}}/\partial e_0 V_{\text{c}}. \quad (8.4)$$

For *real* diodes, the ideality factors n are generally found to be larger than the ideality factor

$$n_{\text{if}} = \left(1 - \frac{\delta\Phi_{\text{if}}^0}{4e_0 |V_{\text{i}}^0|} \right)^{-1}, \quad (8.5)$$

which is determined by the image-force effect only.

The effective barrier heights and the ideality factors of real Schottky diodes fabricated under experimentally identical conditions vary from one specimen to the next. However, the variations of both quantities are correlated, and the $\Phi_{\text{Bn}}^{\text{eff}}$ values become smaller as the ideality factors increase. As an example, Fig. 8.2 displays $\Phi_{\text{Bn}}^{\text{eff}}$ versus n data for Ag/n-Si(111) contacts with $(1 \times 1)^{\text{i}}$ -unreconstructed and $(7 \times 7)^{\text{i}}$ -reconstructed interfaces [8.11]. The dashed and dash-dotted lines are the linear least-squares fits to the data points. The linear dependence of the effective barrier height on the ideality factor may be written as

$$\Phi_{\text{Bn}}^{\text{eff}} = \Phi_{\text{Bn}}^{\text{nif}} - \varphi_{\text{p}}(n - n_{\text{if}}), \quad (8.6)$$

where $\Phi_{\text{Bn}}^{\text{nif}}$ is the barrier height at the ideality factor n_{if} . Several conclusions may be drawn from this relation. First, the $\Phi_{\text{Bn}}^{\text{eff}} - n$ correlation shows that more than

Fig. 8.2 Effective barrier heights versus ideality factors determined from I/V characteristics of Ag/n-Si(111)- $(7 \times 7)^{\text{i}}$ and $-(1 \times 1)^{\text{i}}$ contacts at room temperature. The *dashed* and *dash-dotted* lines are the linear least-squares fits to the data. After [8.11]

one physical mechanism determines the barrier heights of *real* Schottky contacts. Second, the extrapolation of $\Phi_{\text{Bn}}^{\text{eff}}$ versus n curves to n_{if} removes all mechanisms that cause a larger bias dependence of the barrier height than the image-force effect itself from consideration. Third, the extrapolated barrier heights $\Phi_{\text{Bn}}^{\text{nif}}$ are equal to the zero-bias barrier height $\Phi_{\text{Bn}}^{\text{hom}} - \delta\Phi_{\text{if}}^0$ of the laterally homogeneous contact.

The laterally homogeneous barrier heights obtained from $\Phi_{\text{Bn}}^{\text{eff}}$ versus n curves to n_{if} are not necessarily characteristic of the corresponding *ideal* contacts. This is illustrated by the two data sets displayed in Fig. 8.2, which differ in the interface structures of the respective diodes. Quite generally, structural rearrangements such as the $(7 \times 7)^i$ reconstruction are connected with a redistribution of the valence charge. The bonds in perfectly ordered bulk silicon, the example considered here, are purely covalent, and so reconstructions are accompanied by electric $\text{Si}^{+\Delta q} - \text{Si}^{-\Delta q}$ dipoles. The $\text{Si}(111)-(7 \times 7)$ reconstruction is characterized by a stacking fault in one half of its unit mesh [8.16]. *Schmitsdorf* et al. [8.11] quantitatively explained the experimentally observed reduction in the laterally homogeneous barrier height of the $(7 \times 7)^i$ with regard to the $(1 \times 1)^i$ diodes by the electric dipole associated with the stacking fault of the $\text{Si}(111)-7 \times 7$ reconstruction.

Patches of reduced barrier height with lateral dimensions smaller than the depletion layer width that are embedded in large areas of laterally homogeneous barrier height is the only known model that explains a lowering of effective barrier heights with increasing ideality factors. In their phenomenological studies of such patchy Schottky contacts, *Freeouf* et al. [8.12] found that the potential distribution exhibits a saddle point in front of such nanometer-size patches of reduced barrier height. Figure 8.4 explains this behavior. The saddle-point barrier height strongly depends on the voltage drop V_c across the depletion layer. *Freeouf* et al. simulated the current transport in such patchy Schottky contacts and found a reduction in the effective barrier height and a correlated increase in the ideality factor as they reduced the lateral dimensions of the patches. However, they overlooked the fact that the barrier heights of the laterally homogeneous contacts may be obtained from $\Phi_{\text{Bn}}^{\text{eff}}$ versus n plots, by extrapolating to n_{if} .

C/V Characteristics

Both the space charge and the width of the depletion layers at metal–semiconductor contacts vary as a function of the externally applied voltage. The space-charge the-

Fig. 8.3 Calculated potential distribution underneath and around a patch of reduced interface potential embedded in a region of larger interface band-bending. The lateral dimension and the interface potential reduction of the patch are set to two tenths of the depletion layer width z_{dep} and one half of the interface potential of the surrounding region

ory gives the variation in the depletion layer capacitance per unit area as (see [8.14])

$$C_{\text{dep}} = \{e_0^2 \epsilon_b \epsilon_0 N_d / 2 [e_0 (|V_i^0| - V_c) - k_B T]\}^{1/2}. \quad (8.7)$$

The current through a Schottky diode biased in the reverse direction is small, so the *IR* drop due to the series resistance of the diode may be neglected. Consequently, the extrapolated intercepts on the abscissa of $1/C_{\text{dep}}^2$ versus V_a plots give the band bending $e_0 |V_i^0|$ at the interface, and together with the energy distance $W_n = W_F - W_{\text{cb}}$ from the Fermi level to the conduction band minimum in the bulk, one obtains the flat-band barrier height $\Phi_{\text{Bn}}^{\text{fb}} \equiv \Phi_{\text{Bn}}^{\text{hom}} = e_0 |V_i^0| + W_n$ which equals the laterally homogeneous barrier height of the contact.

As an example, Fig. 8.4 displays the flat-band barrier heights of the same $\text{Ag}/n\text{-Si}(111)$ diodes that are discussed in Fig. 8.2. The dashed and dash-dotted lines are the Gaussian least-squares fits to the data from the diodes with $(1 \times 1)^i$ and $(7 \times 7)^i$ interface structures, respectively. Within the margins of experimental error the peak C/V values agree with the laterally homogeneous barrier heights obtained from the extrapolations of the I/V data shown in Fig. 8.2. These data clearly demonstrate that barrier heights characteristic of laterally homogeneous Schottky contacts can be only obtained from I/V or C/V data from many diodes fabricated under identical conditions rather than from a single diode. However, the

Fig. 8.4 Histograms of flat-band barrier heights determined from C/V characteristics of Ag/n-Si(111)-(7×7)ⁱ and -(1×1)ⁱ contacts at room temperature. The data were obtained with the same diodes discussed in Fig. 8.2. The *dashed* and *dash-dotted lines* are the Gaussian least-squares fits to the data. After [8.11]

effective barrier heights and the ideality factors vary as a function of the diode temperature. Hence, effective barrier heights and ideality factors evaluated from the I/V characteristics for one and the same diode recorded at different temperatures are also suitable for determining the corresponding laterally homogeneous barrier height (see [8.14]).

Ballistic-Electron-Emission Microscopy

In ballistic-electron-emission microscopy (BEEM) [8.18], a tip injects almost monoenergetic electrons into the metal film of a Schottky diode. These tunnel-injected electrons reach the semiconductor as ballistic electrons provided that they lose no energy on their way through the metal. Hence, the collector current I_{coll} is expected to set in when the ballistic electrons surpass the metal-semiconductor barrier; in other words, if the voltage V_{tip} applied between tip and metal film exceeds the *local* potential barrier $\Phi_{\text{Bn}}^{\text{loc}}(z)/e_0$. Bell and Kaiser [8.19] derived the square law

$$I_{\text{coll}}(z) = R^* I_{\text{tip}} \left[e_0 V_{\text{tip}} - \Phi_{\text{Bn}}^{\text{loc}}(z) \right]^2 \quad (8.8)$$

for the BEEM $I_{\text{coll}}/V_{\text{tip}}$ characteristics, where I_{tip} is the injected tunnel current. BEEM measures *local* barrier heights; most specifically, the saddle-point barrier heights in front of nanometer-sized patches rather than their lower barrier heights right at the interface.

BEEM is the experimental tool for measuring spatial variations in the barrier height on the nanometer-scale.

Fig. 8.5 Histograms of local BEEM barrier heights of two Pd/n-6H-SiC(0001) diodes with ideality factors of 1.06 (gray solid bars) and 1.49 (empty bars). The data were obtained by fitting the square law (8.8) to 800 BEEM $I_{\text{coll}}/V_{\text{tip}}$ spectra each. Data from Im et al. [8.17]

The local barrier heights are determined by fitting relation (8.8) to measured $I_{\text{coll}}/V_{\text{tip}}$ characteristics recorded at successive tip positions along lateral line scans. Figure 8.5 displays histograms of the local BEEM barrier heights of two Pd/n-6H-SiC(0001) diodes [8.17]. The diodes differ in their ideality factors, 1.06 and 1.49, which are close to and much larger, respectively, than the value $n_{\text{if}} = 1.01$ determined solely by the image-force effect. Obviously, the *nanometer-scale* BEEM histograms of the two diodes are identical although their *macroscopic* ideality factors and therefore their patchiness differ. Two important conclusions were drawn from these findings. First, these data suggest the existence of two different types of patches, intrinsic and extrinsic ones. The intrinsic patches might be correlated with the random distributions of the ionized donors and acceptors which cause nanometer-scale lateral fluctuations in the interface potential. A few gross interface defects of extrinsic origin, which escape BEEM observations, are then responsible for the variations in the ideality factors. Second, Gaussian least-squares fits to the histograms of the local BEEM barrier heights yield peak barrier heights of 1.27 ± 0.03 eV. Within the margins of experimental error, this value agrees with the laterally homogeneous value of 1.24 ± 0.09 eV which was obtained by extrapolation of the linear least-squares fit to a $\Phi_{\text{Bn}}^{\text{eff}}$ versus n plot to n_{if} . The nanometer-scale BEEM histograms and the macroscopic I/V characteristics thus provide identical barrier heights of laterally homogeneous Schottky contacts.

Internal Photoemission Yield Spectroscopy

Metal-semiconductor contacts show a photoelectric response to optical radiation with photon energies smaller than the width of the bulk band gap. This effect is caused by photoexcitation of electrons from the metal over the interfacial barrier into the conduction band of the semiconductor. Experimentally, the internal photoemission yield, which is defined as the ratio of the photoinjected electron flux across the barrier into the semiconductor to the flux of the electrons excited in the metal, is measured as a function of the energy of the incident photons. Consequently, this technique is called internal photoemission yield spectroscopy (IPEYS). *Cohen et al. [8.21]* derived that the internal photoemission yield varies as a function of the photon energy $\hbar\omega$ as

$$Y(\hbar\omega) \propto \left(\hbar\omega - \Phi_{\text{Bn}}^{\text{IPEYS}} \right)^2 / \hbar\omega. \quad (8.9)$$

Patches only cover a small portion of the metal-semiconductor interface, so the threshold energy $\Phi_{\text{Bn}}^{\text{IPEYS}}$ will equal the barrier height $\Phi_{\text{Bn}}^{\text{hom}}$ of the laterally homogeneous part of the contact minus the zero-bias image-force lowering $\delta\Phi_{\text{if}}^0$.

In Fig. 8.6, experimental $[Y(\hbar\omega) \cdot \hbar\omega]^{1/2}$ data for a Pt/p-Si(001) diode [8.20] are plotted versus the energy of the exciting photons. The dashed line is the linear least-squares fit to the data. The deviation of the experimental $[Y(\hbar\omega) \cdot \hbar\omega]^{1/2}$ data towards larger values slightly below and above the threshold is caused by the shape of the Fermi-Dirac distribution function at finite temperatures and by the existence of patches with barrier heights smaller and larger than $\Phi_{\text{Bn}}^{\text{hom}}$.

8.1.2 Band Offsets of Semiconductor Heterostructures

Semiconductors generally grow layer-by-layer, at least initially. Hence, core-level photoemission spectroscopy (PES) is a very reliable tool and the one most widely used to determine the band-structure lineup at semiconductor heterostructures. The valence-band offset may be obtained from the energy positions of core-level lines in X-ray photoelectron spectra recorded with bulk samples of the semiconductors in contact and with the interface itself [8.22]. Since the escape depths of the photoelectrons are on the order of just 2 nm, one of the two semiconductors must be sufficiently thin. This condition is easily met when heterostructures are grown by molecular beam epitaxy (MBE) and PE spectra are recorded during growth interrupts.

Fig. 8.6 Spectral dependence of the internal photoemission yield $\sqrt{Y(\hbar\omega) \cdot \hbar\omega}$ of a Pt/p-Si(001) diode versus the photon energy of the exciting light. The dashed line is the linear least-squares fit to the data for photon energies larger than 0.3 eV. Data from *Turan et al. [8.20]*

The valence-band discontinuity is then given by (see Fig. 8.7)

$$\begin{aligned} \Delta W_v = W_{\text{vir}} - W_{\text{vil}} = & W_i(n_r l_r) - W_i(n_l l_l) \\ & + [W_{\text{vbr}} - W_b(n_r l_r)] - [W_{\text{vbl}} - W_b(n_l l_l)], \end{aligned} \quad (8.10)$$

where $n_r l_r$ and $n_l l_l$ denote the core levels of the semiconductors on the right (r) and the left (l) side of the interface, respectively. The subscripts i and b characterize interface and bulk properties, respectively. The

Fig. 8.7 Schematic energy band diagram at semiconductor heterostructures. W_{vb} and W_{vi} are the valence-band maxima and $W_b(nl)$ and $W_i(nl)$ are the core levels in the bulk and at the interface, respectively. The subscripts l and r denote the semiconductors on the right and the on the left side of the interface. ΔW_v is the valence-band offset. The thin dashed lines account for possible band-bending from space-charge layers

energy difference $W_i(n_r l_r) - W_i(n_l l_l)$ between the core levels of the two semiconductors at the interface is determined from energy distribution curves of photoelectrons recorded during MBE growth of the heterostructure. The energy positions $W_{vbr} - W_b(n_r l_r)$ and $W_{vbl} - W_b(n_l l_l)$ of the core levels relative to the valence-band maxima

in the bulk of the two semiconductors are evaluated separately.

Another widely used technique for determining band offsets in heterostructures is internal photoemission yield spectroscopy. The procedure for evaluating the IPEYS signals is the same as described in Sect. 8.1.1.

8.2 IFIGS- and Electronegativity Theory

Because of the quantum-mechanical tunneling effect, the wavefunctions of bulk electrons decay exponentially into vacuum at surfaces or, more generally speaking, at solid–vacuum interfaces. A similar behavior occurs at interfaces between two solids [8.6, 7]. In energy regions of Schottky contacts and semiconductor heterostructures where occupied band states overlap a band gap, the wavefunctions of these electrons will tail across the interface. The only difference to solid–vacuum interfaces is that the wavefunction tails oscillate at solid–solid interfaces. Figure 8.8 schematically explains the tailing effects at surfaces and semiconductor interfaces. For the band-structure lineup at semiconductor interfaces, only the tailing states within the gap between the top valence and the lowest conduction band are of any real importance since the energy position of the Fermi level determines their charging state. These wavefunction tails or interface-induced gap states (IFIGS) derive from the continuum of the virtual gap states (ViGS) of the complex semiconductor band structure. Hence, the IFIGS are an intrinsic property of the semiconductor.

Fig. 8.8a,b Wavefunctions at clean surfaces (a) and at metal–semiconductor and semiconductor–semiconductor interfaces (b) (schematically)

The IFIGS are made up of valence-band and conduction-band states of the semiconductor. Their net charge depends on the energy position of the Fermi level relative to their branch point, where their character changes from predominantly donor- or valence band-like to mostly acceptor- or conduction band-like. The band-structure lineup at semiconductor interfaces is thus described by a zero-charge-transfer term and an electric dipole contribution.

In a more chemical approach, the charge transfer at semiconductor interfaces may be related to the partly ionic character of the covalent bonds at interfaces. *Pauling* [8.8] described the ionicity of single bonds in diatomic molecules by the difference between the electronegativities of the atoms involved. The binding energies of core-level electrons are known to depend on the chemical environment of the atoms or, in other words, on the ionicity of their chemical bonds. Figure 8.9 displays experimentally observed chemical shifts for Si(2p) and Ge(3d) core levels induced by metal adatoms on silicon and germanium surfaces.

Fig. 8.9 Chemical shifts of Si(2p) and Ge(3d) core levels induced by metal adatoms on silicon and germanium surfaces, respectively, as a function of the difference $X_m - X_s$ in the metal and the semiconductor electronegativities in Pauling units. After [8.14]

on silicon and germanium surfaces as a function of the difference $X_m - X_s$ between the Pauling atomic electronegativity of the metal and that of the semiconductor atoms. The covalent bonds between metal and substrate atoms still persist at metal–semiconductor interfaces, as ab-initio calculations [8.23] have demonstrated for the example of Al/GaAs(110) contacts. The pronounced linear correlation of the data displayed in Fig. 8.9 thus justifies the application of *Pauling's* electronegativity concept to semiconductor interfaces.

The combination of the physical **IFIGS** and the chemical electronegativity concept yields the barrier heights of ideal p-type Schottky contacts and the valence-band offsets of ideal semiconductor heterostructures as

$$\Phi_{\text{Bp}} = \Phi_{\text{bp}}^{\text{p}} - S_X(X_m - X_s) \quad (8.11)$$

and

$$\Delta W_v = \Phi_{\text{bpr}}^{\text{p}} - \Phi_{\text{bpl}}^{\text{p}} + D_X(X_{\text{sr}} - X_{\text{sl}}), \quad (8.12)$$

respectively, where $\Phi_{\text{bp}}^{\text{p}} = W_{\text{bp}} - W_v(\Gamma)$ is the energy distance from the valence-band maximum to the branch point of the **IFIGS** or the p-type branch-point energy. It has the physical meaning of a zero-charge-transfer barrier height. The slope parameters S_X and D_X are explained at the end of this section.

The **IFIGS** derive from the virtual gap states of the complex band structure of the semiconductor. Their branch point is an average property of the semiconductor. *Tersoff* [8.24, 27] calculated the branch-point energies $\Phi_{\text{bp}}^{\text{p}}$ of Si, Ge, and 13 of the III–V and II–VI compound semiconductors. He used a linearized augmented plane-wave method and the local density approximation. Such extensive computations may be avoided. *Mönch* [8.28] applied *Baldereschi's* concept [8.29] of mean-value k -points to calculate the branch-point energies of zincblende-structure compound semiconductors. He first demonstrated that the quasi-particle band gaps of diamond, silicon, germanium, 3C–SiC, GaAs and CdS at the mean-value k -point equal their average or dielectric band gaps [8.30]

$$W_{\text{dg}} = \hbar\omega_p / \sqrt{\epsilon_{\infty} - 1}, \quad (8.13)$$

where $\hbar\omega_p$ is the plasmon energy of the bulk valence electrons. *Mönch* then used *Tersoff's* $\Phi_{\text{bp}}^{\text{p}}$ values, calculated the energy dispersion $W_v(\Gamma) - W_v(k_{\text{mv}})$ of the top-most valence band in the empirical tight-binding approximation (ETB), and plotted the resulting branch-point energies $W_{\text{bp}} - W_v(k_{\text{mv}}) = \Phi_{\text{bp}}^{\text{p}} + [W_v(\Gamma) - W_v(k_{\text{mv}})]_{\text{ETB}}$ at the mean-value k -point k_{mv} versus the widths of the dielectric band gaps W_{dg} . The linear least-squares

fit to the data of the zincblende-structure compound semiconductors [8.28]

$$\Phi_{\text{bp}}^{\text{p}} = 0.449 \cdot W_{\text{dg}} - [W_v(\Gamma) - W_v(k_{\text{mv}})]_{\text{ETB}}, \quad (8.14)$$

indicates that the branch points of these semiconductors lie 5% below the middle of the energy gap at the mean-value k -point. Table 8.1 displays the p-type branch-point energies of the Group IV elemental semiconductors, of SiC, and of III–V and II–VI compound semiconductors, as well as of some insulators.

A simple phenomenological model of Schottky contacts with a continuum of interface states and a constant density of states D_{is} across the semiconductor band gap yields the slope parameter [8.31, 32]

$$S_X = A_X / \left[1 + \left(e_0^2 / \varepsilon_i \varepsilon_0 \right) D_{is} \delta_{is} \right], \quad (8.15)$$

where ε_i is an interface dielectric constant. The parameter A_X depends on the electronegativity scale chosen and amounts to 0.86 eV/Miedema-unit and 1.79 eV/Pauling-unit. For $D_{is} \rightarrow 0$, relation (8.15) yields $S_X \rightarrow 1$ or, in other words, if no interface-induced gap states were present at the metal–semiconductor interfaces one would obtain the Schottky–Mott rule. The extension δ_{is} of the interface states may be approximated by their charge decay length $1/2q_{is}$. Mönch [8.32] used theoretical D_{gs}^{mi} and q_{gs}^{mi} data for metal-induced gap

states (MIGS), as the IFIGS in Schottky contacts are traditionally called, and plotted the $(e_0^2/\varepsilon_0)D_{gs}^{mi}/2q_{gs}^{mi}$ values versus the optical susceptibility $\varepsilon_\infty - 1$. The linear least-squares fit to the data points yielded [8.32]

$$A_X/S_X - 1 = 0.1 \cdot (\varepsilon_\infty - 1)^2, \quad (8.16)$$

where the reasonable assumption $\varepsilon_i \approx 3$ was made.

To a first approximation, the slope parameter D_X of heterostructure band offsets may be equated with the slope parameter S_X of Schottky contacts, since the IFIGS determine the intrinsic electric-dipole contributions to both the valence-band offsets and the barrier heights. Furthermore, the Group IV semiconductors and the elements constituting the III–V and II–VI compound semiconductors are all placed in the center columns of the Periodic Table and their electronegativities thus only differ by up to 10%. Consequently, the electric-dipole term $D_X \cdot (X_{sr} - X_{sl})$ may be neglected [8.9], so that (8.12) reduces to

$$\Delta W_v \cong \Phi_{bpr}^p - \Phi_{bpl}^p \quad (8.17)$$

for practical purposes.

8.3 Comparison of Experiment and Theory

8.3.1 Barrier Heights of Schottky Contacts

Experimental barrier heights of intimate, abrupt, clean and (above all) laterally homogeneous Schottky contacts on n-Si and n-GaAs as well as n-GaN, and the three SiC polytypes 3C, 6H and 4H are plotted in Figs. 8.10 and 8.11, respectively, versus the difference in the Miedema electronegativities of the metals and the semiconductors. Miedema's electronegativities [8.33, 34] are preferred since they were derived from properties of metal alloys and intermetallic compounds, while Pauling [8.8] considered covalent bonds in small molecules. The p- and n-type branch-point energies, $\Phi_{bp}^p = W_{bp} - W_v(\Gamma)$ and $\Phi_{bp}^n = W_c - W_{bp}$, respectively, add up to the fundamental band-gap energy $W_g = W_c - W_v(\Gamma)$. Hence, the barrier heights of n-type Schottky contacts are

$$\Phi_{Bn}^{hom} = \Phi_{bp}^n + S_X(X_m - X_s). \quad (8.18)$$

The electronegativity of a compound is taken as the geometric mean of the electronegativities of its constituent atoms.

First off all, the experimental data plotted in Figs. 8.10 and 8.11 clearly demonstrate that the different

experimental techniques, I/V , BEEM, IPEYS and PES, yield barrier heights of laterally homogeneous Schottky contacts which agree within the margins of experimental error.

Second, all experimental data are quantitatively explained by the branch-point energies (8.14) and the slope parameters (8.16) of the IFIGS-and-electronegativity theory. As was already mentioned in Sect. 8.1.1, the stacking fault, which is part of the interfacial Si(111)-(7×7)ⁱ reconstruction, causes an *extrinsic* electric dipole in addition to the *intrinsic* IFIGS electric dipole. The latter one is present irrespective of whether the interface structure is reconstructed or (1×1)ⁱ-unreconstructed. The extrinsic stacking fault-induced electric dipole quantitatively explains the experimentally observed barrier height lowering of 76 ± 2 meV.

Third, the IFIGS lines in Figs. 8.11a and 8.11b were drawn using the branch-point energies calculated for cubic 3C-GaN and 3C-SiC, respectively, since relation (8.12) was derived for zincblende-structure compounds only. However, the Schottky contacts were prepared on wurtzite-structure 2H-GaN and not just on cubic 3C-SiC but also on its hexagonal polytypes 4H and 6H. The good agreement between the experimen-

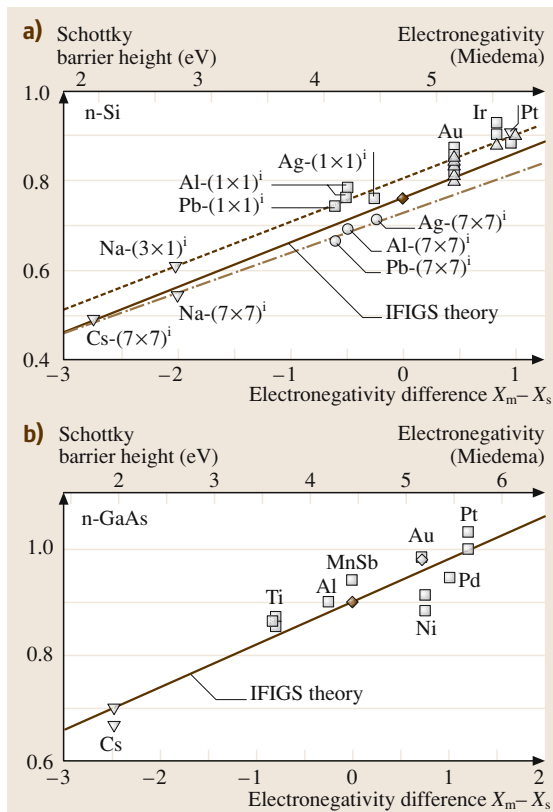

Fig. 8.10a,b Barrier heights of laterally homogeneous n-type silicon (a) and GaAs Schottky contacts (b) versus the difference in the Miedema electronegativities of the metals and the semiconductors. The \circ and \square , \diamond , Δ , and ∇ symbols differentiate the data from *I/V*, *BEEM*, *IPEYS*, and *PES* measurements, respectively. The *dashed* and the *dash-dotted* lines are the linear least-squares fits to the data from diodes with $(1 \times 1)^i$ -unreconstructed and $(7 \times 7)^i$ -reconstructed interfaces, respectively. The *solid IFIGS* lines are drawn with $S_X = 0.101$ eV/Miedema-unit and $\Phi_{bp}^p = 0.36$ eV for silicon (a) and with $S_X = 0.08$ eV/Miedema-unit and $\Phi_{bp}^p = 0.5$ eV for GaAs (b). After [8.14]

tal data and the *IFIGS* lines indicates that the p-type branch-point energies are rather insensitive to the specific bulk lattice structure of the semiconductor. This conclusion is further justified by the band-edge discontinuities of the semiconductor heterostructures, which were experimentally observed and are discussed in Sect. 8.3.2, and by the band-edge offsets of 3C/2H homostructures that were calculated for various semiconductors [8.35–39].

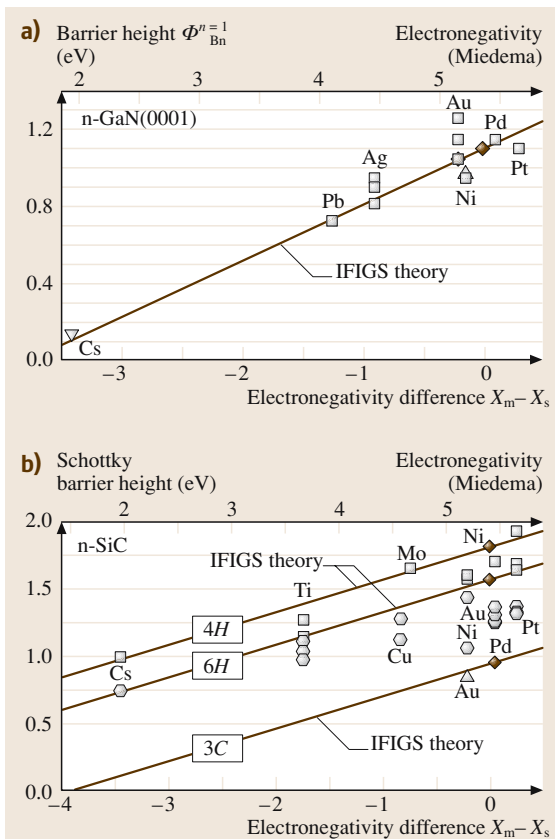

Fig. 8.11a,b Barrier heights of laterally homogeneous n-type GaN(0001) (a) and 3C-, 4H-, and 6H-SiC Schottky contacts (b) versus the difference in the Miedema electronegativities of the metals and the semiconductors. (a): The \square , \diamond , Δ , and ∇ symbols differentiate the data from *I/V*, *BEEM*, *IPEYS*, and *PES* measurements, respectively. The *solid IFIGS* line is drawn with $S_X = 0.29$ eV/Miedema-unit and $\Phi_{bp}^p = 2.37$ eV. (b): The \square , \diamond , and \circ symbols differentiate data of 4H-, 6H- and 3C-SiC Schottky contacts, respectively. The *solid IFIGS* lines are drawn with the band gaps of the polytypes minus $\Phi_{bp}^p = 1.44$ eV of cubic 3C-SiC and $S_X = 0.24$ eV/Miedema-unit. After [8.14]

8.3.2 Band Offsets of Semiconductor Heterostructures

In the bulk, and at interfaces of sp^3 -coordinated semiconductors, the chemical bonds are covalent. The simplest semiconductor–semiconductor interfaces are *lattice-matched* heterostructures. However, if the bond lengths of the two semiconductors differ then the interface will respond with tetragonal lattice distortions. Such

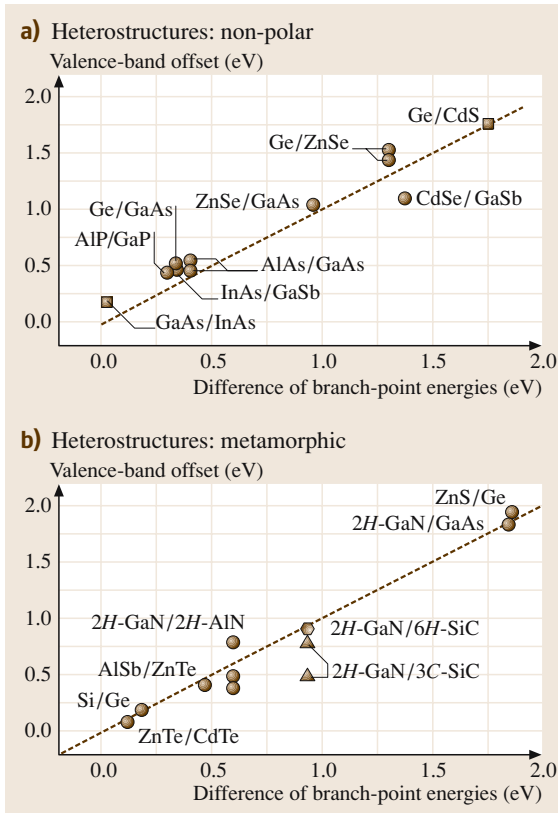

Fig. 8.12a,b Valence band offsets at nonpolar (110)-oriented (a) and metamorphic semiconductor heterostructures (b) versus the difference between the p-type branch-point energies of the semiconductors in contact. After [8.14]

pseudomorphic interfaces are under tensile or compressive stress. If the strain energy becomes too large then it is energetically more favorable to release the stress by the formation of misfit dislocations. Such *metamorphic* interfaces are almost relaxed.

In contrast to isovalent heterostructures, the chemical bonds at heterovalent interfaces require special attention, since interfacial donor- and acceptor-type bonds may cause interfacial electric dipoles [8.40]. No such extrinsic electric dipoles will exist normal to non-polar (110) interfaces. However, polar (001) interfaces behave quite differently. Acceptor bonds or donor bonds normal to the interface would exist at abrupt heterostructures. But, for reasons of charge neutrality, they have to be compensated by a corresponding density of donor bonds and acceptor bonds, respectively. This may be achieved by an intermixing at the interface which, on

the other hand, causes extrinsic electric dipoles. Their components normal to the interface will add an extrinsic electric-dipole contribution to the valence-band offset. In the following, only nonpolar, lattice-matched isovalent, and metamorphic heterostructures will be discussed.

The valence-band offsets at nonpolar, in other words (110)-oriented, heterostructures of compound semiconductors should equal the difference in the branch-point energies of the two semiconductors in contact provided the intrinsic **IFIGS** electric-dipole contribution can be neglected, see relation (8.17). Figure 8.12a displays respective experimental results for diamond- and zincblende-structure semiconductors as a function of the difference in the branch-point energies given in Table 8.1. The dashed line clearly demonstrates that the experimental data are excellently explained by the theoretical branch-point energies or, in other words, by the **IFIGS** theory.

As an example of lattice-matched and isovalent heterostructures, Fig. 8.13 shows valence-band offsets for $\text{Al}_{1-x}\text{Ga}_x\text{As}/\text{GaAs}$ heterostructures as a function of the alloy composition x . The **IFIGS** branch-point energies of the alloys were calculated assuming virtual $\text{Al}_{1-x}\text{Ga}_x$ cations [8.28], and were found to vary linearly as a function of composition between the values of AlAs and GaAs. More refined first-principles calculations yielded identical results [8.41, 42]. Figure 8.13 reveals that the theoretical **IFIGS** valence-band offsets fit the experimental data excellently.

Figure 8.12b displays valence-band offsets for metamorphic heterostructures versus the difference in the branch-point energies of the two semiconductors. The

Fig. 8.13 Valence band offsets of lattice-matched and isovalent $\text{Al}_{1-x}\text{Ga}_x\text{As}/\text{GaAs}$ heterostructures as a function of alloy composition x . After [8.14]

dashed line indicates that the experimental results are again excellently described by the theoretical IFIGS data. This is true not only for heterostructures between cubic zincblende- and hexagonal wurtzite-structure compounds but also for wurtzite-structure Group III nitrides grown on both cubic 3C- and hexagonal 6H-SiC substrates. These observations suggest the following conclusions. First, all of the heterostructures considered in Fig. 8.12b are only slightly (if at all) strained, although their lattice parameters differ by up to 19.8%. Second, the calculations of the IFIGS branch-point energies assumed zincblende-structure semiconductors. These values, on the other hand, reproduce the experimental valence band offsets irrespective of whether the semiconductors have zincblende, wurtzite or, as in the case of 6H-SiC, another hexagonal-polytype structure. These findings again support the conclusion drawn from the GaN and SiC Schottky barrier heights in the previous section, that the IFIGS branch-point energies are rather insensitive to the specific semiconductor bulk lattice structure.

8.3.3 Band-Structure Lineup at Insulator Interfaces

The continuing miniaturization of complementary metal–oxide–semiconductor (CMOS) devices requires gate insulators where the dielectric constants (κ) are larger than the value of the silicon dioxide conventionally used. At present, the high- κ insulators Al_2O_3 , ZrO_2 , and HfO_2 are being intensively studied. Insulators may be considered to be wide-gap semiconductors. Hence, relations (8.11) and (8.12) also apply to insulator Schottky contacts and heterostructures. Unfortunately, the branch-point energies of these insulators cannot be obtained from relation (8.14) since it is valid for zincblende-structure compound semiconductors only. However, the experimental band offsets reported for SiO_2 , Si_3N_4 , Al_2O_3 , and HfO_2 heterostructures may be plotted as a function of the branch-point energies of the respective semiconductors [8.26]. Figure 8.14a reveals that the valence-band offsets become smaller with increasing branch-point energy of the semiconductors. Moreover, the data points reported for the many different SiO_2 heterostructures studied indicate a linear dependence for the valence-band offsets on the branch-point energy of the semiconductors, which may be written as

$$\Delta W_v = \varphi_{\text{vbo}} \left[\Phi_{\text{bp}}^{\text{p}}(\text{ins}) - \Phi_{\text{bp}}^{\text{p}}(\text{sem}) \right], \quad (8.19)$$

since the valence band offsets of insulator homostructures will definitely vanish. Such a linear relationship

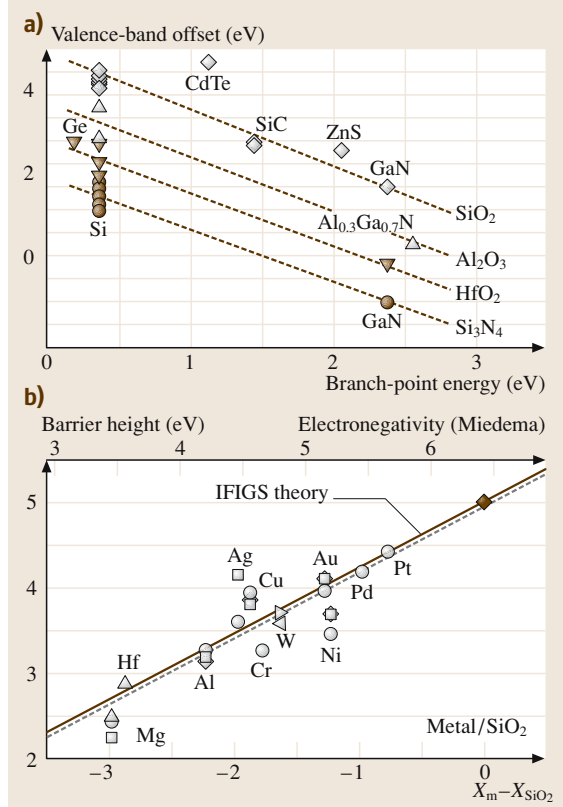

Fig. 8.14 (a) Valence band offsets of SiO_2 , Si_3N_4 , Al_2O_3 and HfO_2 heterostructures versus the p-type branch-point energies of the respective semiconductors. (b) n-type barrier heights of SiO_2 Schottky contacts versus the difference between electronegativities of the metal and SiO_2 . The dashed line is the linear least-squares fit to the data points. The solid IFIGS line is drawn with $\Phi_{\text{bp}}^{\text{p}} = 5 \text{ eV}$ ($W_g = 9 \text{ eV}$) and $S_X = 0.77 \text{ eV/Miedema-unit}$ ($\epsilon_\infty = 2.1$). After [8.25]

can also be adopted for the Al_2O_3 , HfO_2 and Si_3N_4 heterostructures, where less experimental results are available. Hence, the data displayed in Fig. 8.14a provide a means of determining the branch-point energies $\Phi_{\text{bp}}^{\text{p}}(\text{ins})$ of SiO_2 , Si_3N_4 , and the high- κ oxides Al_2O_3 and HfO_2 . The dashed lines in Fig. 8.14a are the linear least-squares fits to the respective data points. The experimental slope parameters φ_{vbo} range from 1.16 to 1.23 for HfO_2 and SiO_2 heterostructures, respectively, while relation (8.12) predicts $\varphi_{\text{vbo}} = 1$ provided that the electric dipole term $D_X \cdot (X_{\text{sr}} - X_{\text{sl}})$ vanishes. However, as well-established as this simplifying assumption is for the classical semiconductor heterostructures discussed in Sect. 8.3.2, it has ques-

tionable validity for the insulators considered here since they are much more ionic. Hence, the difference $\varphi_{\text{vbo}} - 1$ may be attributed to intrinsic electric-dipole layers at these insulator–semiconductor interfaces. The p-type branch-point energies $\Phi_{\text{bp}}^{\text{p}}$ of the insulators obtained from the linear least-squares fits are displayed in Table 8.1.

The reliability of these branch-point energies may be checked by, for example, analyzing barrier heights of respective insulator Schottky contacts. Such data are

only available for SiO_2 . Figure 8.14b displays the barrier heights of SiO_2 Schottky contacts as a function of the electronegativity difference $X_{\text{m}} - X_{\text{SiO}_2}$, where the electronegativity of SiO_2 is estimated as 6.42 Miedema-units. The linear least-squares fit

$$\Phi_{\text{Bn}} = (4.95 \pm 0.19) + (0.77 \pm 0.10) \times (X_{\text{m}} - X_{\text{SiO}_2})[\text{eV}] \quad (8.20)$$

to the experimental data agrees excellently with the prediction from the IFIGS-and-electronegativity theory.

8.4 Final Remarks

The local density approximation to density functional theory (LDA-DFT) is the most powerful and widely used tool in theoretical studies of the ground-state properties of solids. However, excitation energies such as the width of the energy gaps between the valence and conduction bands of semiconductors cannot be correctly obtained from such calculations. The fundamental band gaps of the elemental semiconductors C, Si and Ge as well as of the III–V and II–VI compounds are notoriously underestimated by 25 to 50%. However, it became possible to compute quasi-particle energies and band gaps of semiconductors from first principles using the so-called GW approximation for the electron self-energy [8.43, 44]. The resulting band gap energies agree to within 0.1 to 0.3 eV with experimental values.

For some specific metal–semiconductor contacts, the band-structure lineup was also studied by state-of-the-art ab-initio LDA-DFT calculations. The resulting LDA-DFT barrier heights were then subjected to a-posteriori corrections which consider quasi-particle effects and, if necessary, spin-orbit interactions and semicore-orbital effects. However, comparison of the theoretical results with experimental data gives an inconsistent picture. The *mean* values of the barrier heights of Al- and Zn/p-ZnSe contacts, which were calculated for different interface configurations using ab-initio LDA-DFT theory and a-posteriori spin-orbit and quasi-particle corrections [8.45, 46], agree with the experimental data to within the margins of experimental error. The same conclusion was reached for Al/ $\text{Al}_{1-x}\text{Ga}_x\text{As}$ Schottky

contacts [8.47]. However, ab-initio LDA-DFT barrier heights of Al-, Ag-, and Au/p-GaN contacts [8.48, 49], as well as of Al- and Ti/3C-SiC(001) interfaces [8.50, 51], strongly deviate from the experimental results.

As already mentioned, ab-initio LDF-DFT valence band offsets of $\text{Al}_{1-x}\text{Ga}_x\text{As}/\text{GaAs}$ heterostructures [8.41, 42] reproduce the experimental results well. The same holds for *mean* values of LDF-DFT valence-band offsets computed for different interface configurations of GaN- and AlN/SiC heterostructures [8.52–56].

The main difficulty which the otherwise extremely successful ab-initio LDF-DFT calculations encounter when describing semiconductor interfaces is not the precise exchange-correlation potential, which may be estimated in the GW approximation, but their remarkable sensitivity to the geometrical and compositional structure right at the interface. This aspect is more serious at metal–semiconductor interfaces than at heterostructures between two sp^3 -bonded semiconductors. The more conceptual IFIGS-and-electronegativity theory, on the other hand, quantitatively explains not only the barrier heights of ideal Schottky contacts but also the valence-band offsets of semiconductor heterostructures. Here again, the Schottky contacts are the more important case, since their zero-charge-transfer barrier heights equal the branch-point energies of the semiconductors, while the valence-band offsets are determined by the differences in the branch-point energies of the semiconductors in contact.

9. Charge Transport in Disordered Materials

This chapter surveys general theoretical concepts developed to qualitatively understand and to quantitatively describe the electrical conduction properties of disordered organic and inorganic materials. In particular, these concepts are applied to describe charge transport in amorphous and microcrystalline semiconductors and in conjugated and molecularly doped polymers. Electrical conduction in such systems is achieved through incoherent transitions of charge carriers between spatially localized states. Basic theoretical ideas developed to describe this type of electrical conduction are considered in detail. Particular attention is given to the way the kinetic coefficients depend on temperature, the concentration of localized states, the strength of the applied electric field, and the charge carrier localization length. Charge transport via delocalized states in disordered systems and the relationships between kinetic coefficients under the nonequilibrium conditions are also briefly reviewed.

Many characteristics of charge transport in disordered materials differ markedly from those in perfect crystalline systems. The term “disordered materials” usually refers to noncrystalline solid materials without perfect order in the spatial arrangement of atoms. One should distinguish between disordered materials with ionic conduction and those with electronic conduction. Disordered materials with ionic conduction include various glasses consisting of a “network-formers” such as SiO_2 , B_2O_3 and Al_2O_3 , and of “network-modifiers” such as Na_2O , K_2O and Li_2O . When an external voltage is applied, ions can drift by hopping over potential barriers in the glass matrix, contributing to the electrical conduction of the material. Several fascinating effects have been observed for this kind of electrical conduction. One is the extremely nonlinear dependence of the conductivity on the concentration of ions in the material. Another beautiful phenomenon is the so-called “mixed alkali effect”: mixing two different modifiers in one glass leads to an enormous drop in the conductivity in comparison to that

of a single modifier with the same total concentration of ions. A comprehensive description of these effects can be found in the review article of Bunde et al. [9.1]. Although these effects sometimes appear puzzling, they can be naturally and rather trivially explained using routine classical percolation theory [9.2]. The description of ionic conduction in glasses is much simplified by the inability of ions to tunnel over large distances in the glass matrix in single transitions. Every transition occurs over a rather small interatomic distance, and it is relatively easy to describe such electrical conductivity theoretically [9.2]. On the other hand, disordered systems with electronic conduction have a much more complicated theoretical description. Transition probabilities of electrons between spatially different regions in the material significantly depend not only on the energy parameters (as in the case of ions), but also on spatial factors such as the tunnelling distance, which can be rather large. The interplay between the energy and spatial factors in the transition probabilities of electrons makes the develop-

ment of a theory of electronic conduction in disordered systems challenging. Since the description of electronic conduction is less clear than that of ionic conduction, and since disordered electronic materials are widely used for various device applications, in this chapter we concentrate on disordered materials with the electronic type of electrical conduction.

Semiconductor glasses form one class of such materials. This class includes amorphous selenium, a-Se and other chalcogenide glasses, such as a-As₂Se₃. These materials are usually obtained by quenching from the melt. Another broad class of disordered materials, inorganic amorphous semiconductors, includes amorphous silicon a-Si, amorphous germanium a-Ge, and their alloys. These materials are usually prepared as thin films by the deposition of atomic or molecular species. Hydrogenated amorphous silicon, a-Si:H, has attracted much attention from researchers, since incorporation of hydrogen significantly improves conduction, making it favorable for use in amorphous semiconductor devices. Many other disordered materials, such as hydrogenated amorphous carbon (a-C:H) and its alloys, polycrystalline and microcrystalline silicon are similar to a-Si:H in terms of their charge transport properties. Some crystalline materials can also be considered to be disordered systems. This is the case for doped crystals if transport phenomena within them are determined by randomly distributed impurities, and for mixed crystals with disordered arrangements of various types of atoms in the crystalline lattice. In recent years much research has also been devoted to the study of organic disordered materials, such as conjugated and molecularly doped polymers and organic glasses, since these systems has been shown to possess electronic properties similar to those of inorganic disordered materials, while they are easier to manufacture than the latter systems.

There are two reasons for the great interest of researchers in the conducting properties of disordered materials. On the one hand, disordered systems represent a challenging field in a purely academic sense. For many years the theory of how semiconductors perform charge transport was mostly confined to crystalline systems where the constituent atoms are in regular arrays. The discovery of how to make solid amorphous materials and alloys led to an explosion in measurements of the electronic properties of these new materials. However, the concepts often used in textbooks to describe charge carrier transport in crystalline semiconductors are based on an assumption of long-range order, and so they cannot be applied to electronic transport in disor-

dered materials. It was (and still is) a highly challenging task to develop a consistent theory of charge transport in such systems. On the other hand, the explosion in research into charge transport in disordered materials is related to the various current and potential device applications of such systems. These include the application of disordered inorganic and organic materials in photovoltaics (the functioning material in solar cells), in electrophotography, in large-area displays (they are used in thin film transistors), in electrical switching threshold and memory devices, in light-emitting diodes, in linear image sensors, and in optical recording devices. Readers interested in the device applications of disordered materials should be aware that there are numerous monographs on this topic: the literature on this field is very rich. Several books are recommended (see [9.3–12]), as are numerous review articles referred to in these books.

In this chapter we focus on disordered semiconductor materials, ignoring the broad class of disordered metals. In order to describe electronic transport in disordered metals, one can more or less successfully apply extended and modified conventional theoretical concepts developed for electron transport in ordered crystalline materials, such as the Boltzmann kinetic equation. Therefore, we do not describe electronic transport in disordered metals here. We can recommend a comprehensive monograph to interested readers (see [9.13]), in which modern concepts about conduction in disordered metals are presented beautifully.

Several nice monographs on charge transport in disordered semiconductors are also available. Although many of them were published several years ago (some even decades ago), we can recommend them to the interested reader as a source of information on important experimental results. These results have permitted researchers the present level of understanding of transport phenomena in disordered inorganic and organic materials. A comprehensive collection of experimental data for noncrystalline materials from the books specified above would allow one to obtain a picture of the modern state of experimental research in the field.

We will focus in this chapter on the theoretical description of charge transport in disordered materials, introducing some basic concepts developed to describe electrical conduction. Several excellent books already exist in which a theoretical description of charge transport in disordered materials is the main topic. Among others we can recommend the books of *Shklovskii* and *Efros* [9.14], *Zvyagin* [9.15], *Böttger* and *Bryksin* [9.16], and *Overhof* and *Thomas* [9.17]. There appears to be

a time gap in which comprehensive monographs on the theoretical description of electrical conduction in disordered materials were not published. During this period

some new and rather powerful theoretical concepts were developed. We present these concepts below, along with some more traditional ones.

9.1 General Remarks on Charge Transport in Disordered Materials

Although the literature on transport phenomena in disordered materials is enormously rich, there are still many open questions in this field due to various problems specific to such materials. In contrast to ordered crystalline semiconductors with well-defined electronic energy structures consisting of energy bands and energy gaps, the electronic energy spectra of disordered materials can be treated as quasi-continuous. Instead of bands and gaps, one can distinguish between extended and localized states in disordered materials. In an extended state, the charge carrier wavefunction is spread over the whole volume of a sample, while the wavefunction of a charge carrier is localized in a spatially restricted region in a localized state, and a charge carrier present in such a state cannot spread out in a plane wave as in ordered materials. Actually, localized electron states are known in ordered systems too. Electrons and holes can be spatially localized when they occupy donors or acceptors or some other impurity states or structural defects in ordered crystalline materials. However, the localized states usually appear as δ -like discrete energy levels in the energy spectra of such materials. In disordered semiconductors, on the other hand, energy levels related to spatially localized states usually fill the energy spectrum continuously. The energy that separates the extended states from the localized ones in disordered materials is called the mobility edge. To be precise, we will mostly consider the energy states for electrons in the following. In this case, the states above the mobility edge are extended and the states below the edge are localized. The localized states lie energetically above the extended states for holes. The energy region between the mobility edges for holes and electrons is called the mobility gap. The latter is analogous to the band gap in ordered systems, although the mobility gap contains energy states, namely the spatially localized states. Since the density of states (DOS), defined as the number of states per unit energy per unit volume, usually decreases when the energy moves from the mobility edges toward the center of the mobility gap, the energy regions of localized states in the vicinity of the mobility edges are called band tails. We would like to emphasize that the charge transport properties depend significantly

on the energy spectrum in the vicinity and below the mobility edge (in the band tails). Unfortunately this energy spectrum is not known for almost all disordered materials. A whole variety of optical and electrical investigation techniques have proven unable to determine this spectrum. Since the experimental information on this spectrum is rather vague, it is difficult to develop a consistent theoretical description for charge transport *ab initio*. The absence of reliable information on the energy spectrum and on the structures of the wavefunctions in the vicinity and below the mobility edges can be considered to be the main problem for researchers attempting to quantitatively describe the charge transport properties of disordered materials.

An overview of the energy spectrum in a disordered semiconductor is shown in Fig. 9.1. The energy levels ε_v and ε_c denote the mobility edges for the valence and conduction bands, respectively. Electron states in the mobility gap between these energies are spatially localized. The states below ε_v and above ε_c can be occupied by delocalized holes and electrons. Some peaks in the DOS are shown in the mobility gap, which can be created by some defects with particularly high concentrations. Although there is a consensus between researchers on the general view of the DOS in disordered materials,

Fig. 9.1 Density of states of a noncrystalline semiconductor (schematic); ε_v and ε_c correspond to mobility edges in the conduction band and the valence band, respectively

the particular structure of the energy spectrum is not known for most disordered systems. From a theoretical point of view, it is enormously difficult to calculate this spectrum.

There are several additional problems that make the study of charge transport in disordered materials more difficult than in ordered crystalline semiconductors. The particular spatial arrangements of atoms and molecules in different samples with the same chemical composition can differ from each other depending on the preparation conditions. Hence, when discussing electrical conduction in disordered materials one often should specify the preparation conditions. Another problem is related to the long-time relaxation processes in disordered systems. Usually these systems are not in thermodynamic equilibrium and the slow relaxation of the atoms toward the equilibrium arrangement can lead to some changes in electrical conduction properties. In some disordered materials a long-time electronic relaxation can affect the charge transport properties too, particularly at low temperatures, when electronic spatial rearrangements can be very slow. At low temperatures, when tunneling electron transitions between localized states dominate electrical conduction, this long-time electron relaxation can significantly affect the charge transport properties.

It is fortunate that, despite these problems, some general transport properties of disordered semiconductors have been established. Particular attention is usually paid to the temperature dependence of the electrical conductivity, since this dependence can indicate the underlying transport mechanism. Over a broad temperature range, the direct current (DC) conductivity in disordered materials takes the form

$$\sigma = \sigma_0 \exp \left[- \left(\frac{\Delta(T)}{k_B T} \right)^\beta \right], \quad (9.1)$$

where the pre-exponential factor σ_0 depends on the underlying system and the power exponent β depends on the material and also sometimes on the temperature range over which the conductivity is studied; $\Delta(T)$ is the activation energy. In many disordered materials, like vitreous and amorphous semiconductors, σ_0 is of the order of 10^2 – $10^4 \Omega^{-1} \text{cm}^{-1}$. In such materials the power exponent β is close to unity at temperatures close to and higher than the room temperature, while at lower temperatures β can be significantly smaller than unity. In organic disordered materials, values of β that are larger than unity also have been reported. For such systems the value $\beta \approx 2$ is usually considered to be appropriate [9.18].

Another important characteristic of the electrical properties of a disordered material is its alternating current (AC) conductivity measured when an external alternating electric field with some frequency ω is applied. It has been established in numerous experimental studies that the real part of the AC conductivity in most disordered semiconductors depends on the frequency according to the power law

$$\text{Re } \sigma(\omega) = C \omega^s, \quad (9.2)$$

where C is constant and the power s is usually smaller than unity. This power law has been observed in numerous materials at different temperatures over a wide frequency range. This frequency dependence differs drastically from that predicted by the standard kinetic theory developed for quasi-free charge carriers in crystalline systems. In the latter case, the real part of the AC conductivity has the frequency dependence

$$\text{Re } \sigma(\omega) = \frac{ne^2}{m} \frac{\tau}{1 + \omega^2 \tau^2}, \quad (9.3)$$

where n is the concentration of charge carriers, e is the elementary charge, m is the effective mass and τ is the momentum relaxation time. Since the band electrons in crystalline semiconductors usually have rather short momentum relaxation times, $\tau \approx 10^{-14}$ s, the contribution of charge carriers in delocalized states to the AC conductivity usually does not depend on frequency at $\omega \ll \tau^{-1}$. Therefore, the observed frequency dependence described by (9.2) should be ascribed to the contribution of charge carriers in localized states.

One of the most powerful tools used to study the concentrations of charge carriers and their mobilities in crystalline semiconductors is the provided by measurements of the Hall constant, R_H . Such measurements also provide direct and reliable information about the sign of the charge carriers in crystalline materials. Unfortunately, this is not the case for disordered materials. Moreover, several anomalies have been established for Hall measurements in the latter systems. For example, the sign of the Hall constant in disordered materials sometimes differs from that of the thermoelectric power, α . This anomaly has not been observed in crystalline materials. The anomaly has been observed in liquid and solid noncrystalline semiconductors. Also, in some materials, like amorphous arsenic, a-As, $R_H > 0$, $\alpha < 0$, while in many other materials other combinations with different signs of R_H and α have been experimentally established.

In order to develop a theoretical picture of the transport properties of any material, the first issues to clarify

are the spectrum of the energy states for charge carriers and the spatial structure of such states. Since these two central issues are yet to be answered properly for noncrystalline materials, the theory of charge transport in disordered systems should be considered to be still in its embryonic stage.

The problem of deducing electron properties in a random field is very complicated, and the solutions obtained so far only apply to some very simple models. One of them is the famous Anderson model that illustrates the localization phenomenon caused by random disorder [9.19]. In this model, one considers a regular system of rectangular potential wells with randomly varying depths, as shown schematically in Fig. 9.2. The ground state energies of the wells are assumed to be randomly distributed over the range with a width of W . First, one considers the ordered version of the model, with W equal to zero. According to conventional band theory, a narrow band arises in the ordered system where the energy width depends on the overlap integral I between the electron wavefunctions in the adjoining

Fig. 9.2 Anderson model of disorder potential

Fig. 9.3 Density of states in the Anderson model. *Hatched regions in the tails correspond to spatially localized states*

wells. The eigenstates in such a model are delocalized with wavefunctions of the Bloch type. This is trivial. The problem is to find the solution for a finite degree of disorder ($W \neq 0$). The result from the Anderson model for such a case is described as follows. At some particular value for the ratio $W/(zI)$, where z is the coordination number of the lattice, all electron states of the system are spatially localized. At smaller values of $W/(zI)$ some states in the outer regions of the DOS are localized and other states in the middle of the DOS energy distribution are spatially extended, as shown schematically in Fig. 9.3. This is one of the most famous results in the transport theory of disordered systems. When considering this result, one should note the following points. (i) It was obtained using a single-electron picture without taking into account long-range many-particle interactions. However, in disordered systems with localized electrons such interactions can lead to the localization of charge carriers and they often drastically influence the energy spectrum [9.14]. Therefore the applicability of the single-electron Anderson result to real systems is questionable. (ii) Furthermore, the energy structure of the Anderson model shown in Fig. 9.3 strongly contradicts that observed in real disordered materials. In real systems, the mobility gap is located between the mobility edges, as shown in Fig. 9.1, while in the Anderson model the energy region between the mobility edges is filled with delocalized states. Moreover, in one-dimensional and in some two-dimensional systems, the Anderson model predicts that all states are localized at any amount of disorder. These results are of little help when attempting to interpret the DOS scheme in Fig. 9.1.

A different approach to the localization problem is to try to impose a random potential $V(x)$ onto the band structure obtained in the frame of a traditional band theory. Assuming a classical smoothly varying (in space)

Fig. 9.4a–c Disorder potential landscape experienced by a charge carrier (a). Regions with energies below some given energy level E_c are colored black. In frame (b) this level is very low and there is no connected path through the system via black regions. In frame (c) the level E_c corresponds to the classical percolation level

potential $V(x)$ with a Gaussian distribution function

$$F(V) = \frac{1}{\varepsilon_0 \sqrt{2\pi}} \exp\left(-\frac{V^2}{2\varepsilon_0^2}\right), \quad (9.4)$$

one can solve the localization problem using the classical percolation theory illustrated in Fig. 9.4. In Fig. 9.4a, an example of a disorder potential experienced by electrons is shown schematically. In Fig. 9.4b and Fig. 9.4c the regions below a given energy level E_c are colored black. In Fig. 9.4b this level is positioned very low, so that regions with energies below E_c do not provide a connected path through the system. In Fig. 9.4c an infinite percolation cluster consisting only of black regions exists. The E_c that corresponds to the first appearance of such a connected path is called the classical percolation level [9.14]. Mathematically solving the percolation problem shows that the mobility edge identified with the classical percolation level in the potential $V(x)$ is shifted with respect to the band edge of the ordered system by an amount $\xi\varepsilon_0$, where $\xi \approx 0.96$ towards the center of the bandgap [9.15]. A similar result, though with a different constant ξ , can be obtained via a quantum-mechanical treatment of a short-range potential $V(x)$ of white-noise type [9.20]. As the amplitude ε_0 of the random potential increases the band gap narrows, while the conduction and valence bands become broader. Although this result is provided by both limiting models – by the classical one with a long-range smoothly varying potential $V(x)$ and by the quantum-mechanical one with a short-range white-noise potential $V(x)$ – none of the existing theories can reliably describe the energy spectrum of a disordered material and the properties of the charge carrier wavefunctions in the vicinity of the mobility edges, in other words in the energy range which is most important for charge transport.

The DC conductivity can generally be represented in the form

$$\sigma = e \int \mu(\varepsilon) n(\varepsilon) d\varepsilon, \quad (9.5)$$

where e is the elementary charge, $n(\varepsilon)d\varepsilon$ is the concentration of electrons in the energy range between ε and $\varepsilon + d\varepsilon$ and $\mu(\varepsilon)$ is the mobility of these electrons. The integration is carried out over all energies ε . Under equilibrium conditions, the concentration of electrons $n(\varepsilon)d\varepsilon$ is determined by the density of states $g(\varepsilon)$ and the Fermi function $f(\varepsilon)$, which depends on the position of the Fermi energy ε_F (or a quasi-Fermi energy in the case of the stationary excitation of electrons):

$$n(\varepsilon) = g(\varepsilon) f(\varepsilon), \quad (9.6)$$

where

$$f(\varepsilon) = \frac{1}{1 + \exp\left(\frac{\varepsilon - \varepsilon_F}{k_B T}\right)}. \quad (9.7)$$

Here T is the temperature and k_B is the Boltzmann constant.

The Fermi level in almost all known disordered semiconductors under real conditions is situated in the mobility gap – in the energy range which corresponds to spatially localized electron states. The charge carrier mobility $\mu(\varepsilon)$ in the localized states below the mobility edge is much less than that in the extended states above the mobility edge. Therefore, at high temperatures, when a considerable fraction of electrons can be found in the delocalized states above the mobility edge, these states dominate the electrical conductivity of the system. The corresponding transport mechanism under such conditions is similar to that in ordered crystalline semiconductors. Electrons in the states within the energy range of the width, of the order $k_B T$ above the mobility edge, dominate the conductivity. In such a case the conductivity can be estimated as

$$\sigma \approx e \mu_c n(\varepsilon_c) k_B T, \quad (9.8)$$

where μ_c is the electron mobility in the states above the mobility edge ε_c , and $n(\varepsilon_c)k_B T$ is their concentration. This equation is valid under the assumption that the typical energy scale of the DOS function $g(\varepsilon)$ above the mobility edge is larger than $k_B T$. The position of the Fermi level in disordered materials usually depends on temperature only slightly. Combining (9.6)–(9.8), one obtains the temperature dependence of the DC conductivity in the form

$$\sigma = \sigma_0 \exp\left(-\frac{\Delta}{k_B T}\right), \quad (9.9)$$

described by (9.1) with $\beta = 1$ and constant activation energy, which is observed in most disordered semiconductors at high temperatures.

In order to obtain the numerical value of the conductivity in this high-temperature regime, one needs to know the density of states in the vicinity of the mobility edge $g(\varepsilon_c)$, and also the magnitude of the electron mobility μ_c in the delocalized states above ε_c . While the magnitude of $g(\varepsilon_c)$ is usually believed to be close to the DOS value in the vicinity of the band edge in crystalline semiconductors, there is no consensus among researchers on the magnitude of μ_c . In amorphous semiconductors μ_c is usually estimated to be in the range of $1 \text{ cm}^2/\text{Vs}$ to $10 \text{ cm}^2/\text{Vs}$. Unfortunately, there are no reliable theoretical calculations of this quantity for most disordered

materials. The only exception is provided by so-called mixed crystals, which are also sometimes called crystalline solid solutions. In the next section we describe the theoretical method which allows one to estimate μ_c in

such systems. This method can be extended to other disordered materials, provided the statistical properties of the disorder potential, essential for electron scattering, are known.

9.2 Charge Transport in Disordered Materials via Extended States

The states with energies below ε_v and above ε_c in disordered materials are believed to possess similar properties to those of extended states in crystals. Various experimental data suggest that these states in disordered materials are delocalized states. However, traditional band theory is largely dependent upon the system having translational symmetry. It is the periodic atomic structure of crystals that allows one to describe electrons and holes within such a theory as quasi-particles that exhibit behavior similar to that of free particles in vacuum, albeit with a renormalized mass (the so-called “effective mass”). The energy states of such quasi-particles can be described by their momentum values. The wavefunctions of electrons in these states (the so-called Bloch functions) are delocalized. This means that the probability of finding an electron with a given momentum is equal at corresponding points of all elementary cells of the crystal, independent on the distance between the cells.

Strictly speaking, the traditional band theory fails in the absence of translational symmetry – for disordered systems. Nevertheless, one still assumes that the charge carriers present in delocalized states in disordered materials can be approximately described by wavefunctions with a spatially homogeneous probability of finding a charge carrier with a given quasi-momentum. As for crystals, one starts from the quasi-free particle picture and considers the scattering effects in a perturbation approach following the Boltzmann kinetic description. This description is valid if the de Broglie wavelength of the charge carrier $\lambda = \hbar/p$ is much less than the mean free path $l = v\tau$, where τ is the momentum relaxation time and p and v are the characteristic values of the momentum and velocity, respectively. This validity condition for the description based on the kinetic Boltzmann equation can also be expressed as $\hbar/\tau \ll \varepsilon$, where ε is the characteristic kinetic energy of the charge carriers, which is equal to $k_B T$ for a nondegenerate electron gas and to the Fermi energy in the degenerate case. While this description seems valid for delocalized states far from the mobility edges, it fails for energy states in the vicinity of the mobility edges. So far, there has been

no consensus between the theorists on how to describe charge carrier transport in the latter states. Moreover, it is not clear whether the energy at which the carrier mobility drops coincides with the mobility edge or whether it is located above the edge in the extended states. Numerous discussions of this question, mostly based on the scaling theory of localization, can be found in special review papers. For the rest of this section, we skip this rather complicated subject and instead we focus on the description of charge carrier transport in a semiconductor with a short-range random disorder potential of white-noise type. This seems to be the only disordered system where a reliable theory exists for charge carrier mobility via extended states above the mobility edge. Semiconductor solid solutions provide an example of a system with this kind of random disorder [9.20–25].

Semiconductor solid solutions $A_x B_{1-x}$ (mixed crystals) are crystalline semiconductors in which the sites of the crystalline sublattice can be occupied by atoms of two different types, A and B. Each site can be occupied by either an A or a B atom with some given probability x between zero and unity. The value x is often called the composition of the material. Due to the random spatial distributions of the A and B atoms, local statistical fluctuations in the composition inside the sample are unavoidable, meaning that mixed crystals are disordered systems. Since the position of the band edge depends on the composition x , these fluctuations in local x values lead to the disorder potential for electrons and holes within the crystal. To be precise, we will consider the influence of the random potential on a conduction band electron. Let $E_c(x)$ be the conduction band minimum for a crystal with composition x . In Fig. 9.5 a possible schematic dependence $E_c(x)$ is shown. If the average composition for the whole sample is x_0 , the local positions of the band edge $E_c(x)$ fluctuate around the average value $E_c(x_0)$ according to the fluctuations of the composition x around x_0 . For small deviations in composition Δx from the average value, one can use the linear relation

$$E_c(x_0 + \Delta x) = E_c(x_0) + \alpha \Delta x, \quad (9.10)$$

Fig. 9.5 Schematic dependence of the conduction band edge ε_c on composition x in a mixed crystal A_xB_{1-x}

where

$$\alpha = \left. \frac{dE_c(x)}{dx} \right|_{x=x_0}. \quad (9.11)$$

If the deviation of the concentration of A atoms from its mean value in some region of a sample is $\xi(r)$ and the total concentration of (sub)lattice sites is N , the deviation of the composition in this region is $\Delta x = \xi(r)/N$, and the potential energy of an electron at the bottom of the conduction band is

$$V(r) = \alpha \frac{\xi(r)}{N}. \quad (9.12)$$

Although one calls the disorder in such systems a “short-range” disorder, it should be noted that the consideration is valid only for fluctuations that are much larger than the lattice constant of the material. The term “short-range” is due to the assumption that the statistical properties of the disorder are absolutely uncorrelated. This means that potential amplitudes in the adjoining spatial points are completely uncorrelated to each other. Indeed, it is usually assumed that the correlation function of the disorder in mixed crystals can be approximated by a white-noise correlation function of the form

$$\langle \xi(r)\xi(r') \rangle = x(1-x)N\delta(r-r'). \quad (9.13)$$

The random potential caused by such compositional fluctuations is then described by the correlation function [9.20]

$$\langle V(r)V(r') \rangle = \gamma\delta(r-r') \quad (9.14)$$

with

$$\gamma = \frac{\alpha^2}{N}x(1-x). \quad (9.15)$$

Charge carriers in mixed crystals are scattered by compositional fluctuations. As is usual in kinetic descriptions of free electrons, the fluctuations on the spatial scale of the order of the electron wavelength are most efficient. Following *Shlimak et al.* [9.23], consider an isotropic quadratic energy spectrum

$$\varepsilon_p = \frac{p^2}{2m}, \quad (9.16)$$

where p and m are the quasi-momentum and the effective mass of an electron, respectively. The scattering rate for such an electron is

$$v_p = \frac{2\pi}{\hbar} \sum_q \langle |V_q|^2 \rangle (1 - \cos \vartheta_q) \delta(\varepsilon_p - \varepsilon_{p-q}), \quad (9.17)$$

where ϑ_q is the scattering angle and

$$\langle |V_q|^2 \rangle = \frac{1}{\Omega} \int d^3r \exp(iqr) \langle V(r)V(0) \rangle. \quad (9.18)$$

The quantity Ω in this formula is the normalization volume. Using the correlation function (9.14), one obtains the relation

$$\langle |V_q|^2 \rangle = \frac{\alpha^2 x(1-x)}{\Omega N}, \quad (9.19)$$

which shows that the scattering by compositional fluctuations is equivalent to that by a short-range potential [9.23]. Substituting (9.19) into (9.17) one obtains the following expression for the scattering rate [9.20]

$$v_p = \frac{\alpha^2 x(1-x)mp}{\pi \hbar^4 N}. \quad (9.20)$$

This formula leads to an electron mobility of the following form in the framework of the standard Drude approach [9.20, 23]

$$\mu_C = \frac{\pi^{3/2}}{2\sqrt{2}} \frac{e\hbar^4 N}{\alpha^2 x(1-x)m^{5/2}(k_B T)^{1/2}}. \quad (9.21)$$

Very similar formulae can be found in many recent publications (see for example *Fahy and O'Reilly* [9.26]). It has also been modified and applied to two-dimensional systems [9.27] and to disordered diluted magnetic semiconductors [9.28].

It would not be difficult to apply this theoretical description to other disordered systems, provided the correlation function of the disorder potential takes the form of (9.14) with known amplitude γ . However, it is worth emphasizing that the short-range disorder of white-noise type considered here is a rather simple

model that cannot be applied to most disordered materials. Therefore, we can conclude that the problem of theoretically describing charge carrier mobility via delocalized states in disordered materials is still waiting to be solved.

9.3 Hopping Charge Transport in Disordered Materials via Localized States

Electron transport via delocalized states above the mobility edge dominates the electrical conduction of disordered materials only at temperatures high enough to cause a significant fraction of the charge carriers fill these states. As the temperature decreases, the concentration of the electrons described by (9.9) decreases exponentially and so their contribution to electrical conductivity diminishes. Under these circumstances, tunneling transitions of electrons between localized states in the band tails dominate the charge transport in disordered semiconductors. This transport regime is called hopping conduction, since the incoherent sequence of tunneling transitions of charge carriers resembles a series of their hops between randomly distributed sites. Each site in this picture provides a spatially localized electron state with some energy ε . In the following we will assume that the localized states for electrons (concentration N_0) are randomly distributed in space and their energy distribution is described by the DOS function $g(\varepsilon)$:

$$g(\varepsilon) = \frac{N_0}{\varepsilon_0} G\left(\frac{\varepsilon}{\varepsilon_0}\right), \quad (9.22)$$

where ε_0 is the energy scale of the DOS distribution.

The tunneling transition probability of an electron from a localized state i to a localized state j that is lower in energy depends on the spatial separation r_{ij} between the sites i and j as

$$v_{ij}(r) = v_0 \exp\left(-\frac{2r_{ij}}{\alpha}\right), \quad (9.23)$$

where α is the localization length, which we assume to be equal for sites i and j . This length determines the exponential decay of the electron wavefunction in the localized states, as shown in Fig. 9.6. The pre-exponential factor v_0 in (9.23) depends on the electron interaction mechanism that causes the transition. Usually it is assumed that electron transitions contributing to charge transport in disordered materials are caused by interactions of electrons with phonons. Often the coefficient v_0 is simply assumed to be of the order of the phonon

In the following section we present the general concepts developed to describe electrical conduction in disordered solids at temperatures where tunneling transitions of electrons between localized states significantly contribute to charge transport.

Fig. 9.6 Hopping transition between two localized states i and j with energies of ε_i and ε_j , respectively. The *solid* and *dashed* lines depict the carrier wavefunctions at sites i and j , respectively; α is the localization radius

frequency ($\approx 10^{13} \text{ s}^{-1}$), although a more rigorous approach is in fact necessary to determine v_0 . This should take into account the particular structure of the electron localized states and also the details of the interaction mechanism [9.29, 30].

When an electron transits from a localized state i to a localized state j that is higher in energy, the transition rate depends on the energy difference between the states. This difference is compensated for by absorbing a phonon with the corresponding energy [9.31]:

$$v_{ij}(r, \varepsilon_i, \varepsilon_j) = v_0 \exp\left(-\frac{2r_{ij}}{\alpha}\right) \times \exp\left(-\frac{\varepsilon_j - \varepsilon_i + |\varepsilon_j - \varepsilon_i|}{2k_B T}\right). \quad (9.24)$$

Equations (9.23) and (9.24) were written for the case in which the electron occupies site i whereas site j is empty. If the system is in thermal equilibrium, the occupation probabilities of sites with different energies are determined by Fermi statistics. This effect can be taken into account by modifying (9.24) and adding terms that account for the relative energy positions of sites i and

j with respect to the Fermi energy ε_F . Taking into account these occupation probabilities, one can write the transition rate between sites i and j in the form [9.31]

$$v_{ij} = v_0 \exp\left(-\frac{2r_{ij}}{a}\right) \times \exp\left(-\frac{|\varepsilon_i - \varepsilon_F| + |\varepsilon_j - \varepsilon_F| + |\varepsilon_j - \varepsilon_i|}{2k_B T}\right). \quad (9.25)$$

Using these formulae, the theoretical description of hopping conduction is easily formulated. One has to calculate the conductivity provided by transition events (the rates of which are described by (9.25)) in the manifold of localized states (where the DOS is described by (9.22)).

9.3.1 Nearest-Neighbor Hopping

Before presenting the correct solution to the hopping problem we would like to emphasize the following. The style of the theory for electron transport in disordered materials via localized states significantly differs from that used for theories of electron transport in ordered crystalline materials. While the description is usually based on various averaging procedures in crystalline systems, in disordered systems these averaging procedures can lead to extremely erroneous results. We believe that it is instructive to analyze some of these approaches in order to illustrate the differences between the descriptions of charge transport in ordered and disordered materials. To treat the scattering rates of electrons in ordered crystalline materials, one usually proceeds by averaging the scattering rates over the ensemble of scattering events. A similar procedure is often attempted for disordered systems too, although various textbooks (see, for instance, *Shklovskii and Efros* [9.14]) illustrate how erroneous such an approach can be in the case of disordered materials.

Let us consider the simplest example of hopping processes, namely the hopping of an electron through a system of isoenergetic sites randomly distributed in space with some concentration N_0 . It will be always assumed in this chapter that electron states are strongly localized and the strong inequality $N_0\alpha^3 \ll 1$ is fulfilled. In such a case the electrons prefer to hop between the spatially nearest sites and therefore this transport regime is often called nearest-neighbor hopping (NNH). This type of hopping transport takes place in many real systems at temperatures where the thermal energy $k_B T$ is larger than the energy scale of the DOS. In such sit-

uations the energy-dependent terms in (9.24) and (9.25) do not play any significant role and the hopping rates are determined solely by the spatial terms. The rate of transition of an electron between two sites i and j is described in this case by (9.23). The average transition rate is usually obtained by weighting this expression with the probability of finding the nearest neighbor at some particular distance r_{ij} , and by integrating over all possible distances:

$$\begin{aligned} \langle v \rangle &= \int_0^\infty dr v_0 \\ &\times \exp\left(-\frac{2r}{\alpha}\right) 4\pi r^2 N_0 \exp\left(-\frac{4\pi}{3} r^3 N_0\right) \\ &\approx \pi v_0 N_0 \alpha^3. \end{aligned} \quad (9.26)$$

Assuming that this average hopping rate describes the mobility, diffusivity and conductivity of charge carriers, one apparently comes to the conclusion that these quantities are linearly proportional to the density of localized states N_0 . However, experiments evidence an exponential dependence of the transport coefficients on N_0 .

Let us look therefore at the correct solution to the problem. This solution is provided in the case considered here, $N_0\alpha^3 \ll 1$, by percolation theory (see, for instance, *Shklovskii and Efros* [9.14]). In order to find the transport path, one connects each pair of sites if the relative separation between the sites is smaller than some given distance R , and checks whether there is a continuous path through the system via such sites. If such a path is absent, the magnitude of R is increased and the procedure is repeated. At some particular value $R = R_c$, a continuous path through the infinite system via sites with relative separations $R < R_c$ arises. Various mathematical considerations give the following relation for R_c [9.14]:

$$\frac{4\pi}{3} N_0 R_c^3 = B_c, \quad (9.27)$$

where $B_c = 2.7 \pm 0.1$ is the average number of neighboring sites available within a distance of less than R_c . The corresponding value of R_c should be inserted into (9.23) in order to determine kinetic coefficients such as the mobility, diffusivity and conductivity. The idea behind this procedure is as follows. Due to the exponential dependence of the transition rates on the distances between the sites, the rates for electron transitions over distances $r < R_c$ are much larger than those over distances R_c . Such fast transitions do not play any significant role as a limiting factor in electron transport and so they can

Fig. 9.7 A typical transport path with the lowest resistance. Circles depict localized states. The arrow points out the most “difficult” transition, with length R_c

be neglected in calculations of the resistivity of the system. Transitions over distances R_c are the slowest among those that are necessary for DC transport and hence such transitions determine the conductivity. The structure of the percolation cluster responsible for charge transport is shown schematically in Fig. 9.7. The transport path consists of quasi-one-dimensional segments, each containing a “difficult” transition over the distance $\approx R_c$. Using (9.23) and (9.27), one obtains the dependence of the conductivity on the concentration of localization sites in the form

$$\sigma = \sigma_0 \exp\left(-\frac{\gamma}{\alpha N_0^{1/3}}\right), \quad (9.28)$$

where σ_0 is the concentration-independent pre-exponential factor and $\gamma = 1.73 \pm 0.03$. Such arguments do not allow one to determine the exponent in the kinetic coefficients with an accuracy better than a number of the order of unity [9.14]. One should note that the quantity in the exponent in (9.28) is much larger than unity for a system with strongly localized states when the inequality $N_0 \alpha^3 \ll 1$ is valid. This inequality justifies the above derivation. The dependence described by (9.28) has been confirmed in numerous experimental studies of the hopping conductivity via randomly placed impurity atoms in doped crystalline semiconductors [9.14]. The drastic difference between this correct result and the erroneous one based on (9.26) is apparent. Unfortunately, the be-

lief of many researchers in the validity of the procedure based on the averaging of hopping rates is so strong that the agreement between (9.28) and experimental data is often called occasional. We would like to emphasize once more that the ensemble averaging of hopping rates leads to erroneous results. The magnitude of the average rate in (9.26) is dominated by rare configurations of very close pairs of sites with separations of the order of the localization length α . Of course, such pairs allow very fast electron transitions, but electrons cannot move over considerable distances using only these close pairs. Therefore the magnitude of the average transition rate is irrelevant for calculations of the hopping conductivity. The correct concentration dependence of the conductivity is given by (9.28). This result was obtained under the assumption that only spatial factors determine transition rates of electrons via localized states. This regime is valid at reasonably high temperatures.

If the temperature is not as high and the thermal energy $k_B T$ is smaller than the energy spread of the localized states involved in the charge transport process, the problem of calculating the hopping conductivity becomes much more complicated. In this case, the interplay between the energy-dependent and the distance-dependent terms in (9.24) and (9.25) determines the conductivity. The lower the temperature, the more important the energy-dependent terms in the expressions for transition probabilities of electrons in (9.24) and (9.25) become. If the spatially nearest-neighboring sites have very different energies, as shown in Fig. 9.8, the probability of an upward electron transition between these sites can be so low that it would be more favorable for this electron to hop to a more distant site at a closer energy. Hence the typical lengths of

Fig. 9.8 Two alternative hopping transitions between occupied states (filled circles) and unoccupied states. The dashed line depicts the position of the Fermi level. Transitions (1) and (2) correspond to nearest-neighbor hopping and variable-range hopping regimes, respectively

electron transitions increase with decreasing temperature. This transport regime was termed “variable-range hopping”. Next we describe several useful concepts developed to describe this transport regime.

9.3.2 Variable-Range Hopping

The concept of variable-range hopping (VRH) was put forward by Mott (see *Mott and Davis* [9.32]) who considered electron transport via a system of randomly distributed localized states at low temperatures. We start by presenting Mott’s arguments. At low temperatures, electron transitions between states with energies in the vicinity of the Fermi level are most efficient for transport since filled and empty states with close energies can only be found in this energy range. Consider the hopping conductivity resulting from energy levels within a narrow energy strip with width $2\Delta\varepsilon$ symmetric to the Fermi level shown in Fig. 9.9. The energy width of the strip useful for electron transport can be determined from the relation

$$g(\varepsilon_F) \cdot \Delta\varepsilon \cdot r^3(\Delta\varepsilon) \approx 1. \quad (9.29)$$

This criterion is similar to that used in (9.27), although we do not care about numerical coefficients here. Here we have to consider the percolation problem in four-dimensional space since in addition to the spatial terms considered in Sect. 9.3.1 we now have to consider the energy too. The corresponding percolation problem for the transition rates described by (9.25) has not yet been solved precisely. In (9.29) it is assumed that the energy width $2\Delta\varepsilon$ is rather small and that the DOS function $g(\varepsilon)$ is almost constant in the range $\varepsilon_F \pm \Delta\varepsilon$. One can obtain

Fig. 9.9 Effective region in the vicinity of the Fermi level where charge transport takes place at low temperatures

the typical hopping distance from (9.29) as a function of the energy width $\Delta\varepsilon$ in the form

$$r(\Delta\varepsilon) \approx [g(\varepsilon_F)\Delta\varepsilon]^{-1/3}, \quad (9.30)$$

and substitute it into (9.24) in order to express the typical hopping rate

$$\nu = \nu_0 \exp\left(-\frac{2[g(\varepsilon_F)\Delta\varepsilon]^{-1/3}}{\alpha} - \frac{\Delta\varepsilon}{k_B T}\right). \quad (9.31)$$

The optimal energy width $\Delta\varepsilon$ that provides the maximum hopping rate can be determined from the condition $d\nu/d\Delta\varepsilon = 0$. The result reads

$$\Delta\varepsilon = \left(\frac{2k_B T}{3g^{1/3}(\varepsilon_F)}\right)^{3/4}. \quad (9.32)$$

After substitution of (9.32) into (9.31) one obtains Mott’s famous formula for temperature-dependent conductivity in the VRH regime

$$\sigma = \sigma_0 \exp\left[-\left(\frac{T_0}{T}\right)^{1/4}\right], \quad (9.33)$$

where T_0 is the characteristic temperature:

$$T_0 = \frac{\beta}{k_B g(\varepsilon_F) \alpha^3}. \quad (9.34)$$

Mott gave only a semi-quantitative derivation of (9.33), from which the exact value of the numerical constant β cannot be determined. Various theoretical studies in 3-D systems suggest values for β in the range $\beta = 10.0$ to $\beta = 37.8$. According to our computer simulations, the appropriate value is close to $\beta = 17.6$.

Mott’s law implies that the density of states in the vicinity of the Fermi level is energy-independent. However, it is known that long-range electron–electron interactions in a system of localized electrons cause a gap (the so-called Coulomb gap) in the DOS in the vicinity of the Fermi energy [9.33, 34]. The gap is shown schematically in Fig. 9.10. Using simple semiquantitative arguments, *Efros and Shklovskii* [9.33] suggested a parabolic shape for the DOS function

$$g(\varepsilon) = \frac{\eta \kappa^3}{e^6} (\varepsilon - \varepsilon_F)^2, \quad (9.35)$$

where κ is the dielectric constant, e is the elementary charge and η is a numerical coefficient. This result was later confirmed by numerous computer simulations (see, for example, *Baranovskii et al.* [9.35]). At low temperatures, the density of states near the Fermi level has a parabolic shape, and it vanishes exactly at the Fermi

energy. As the temperature rises, the gap disappears (see, for example, *Shlimak et al.* [9.36]).

As we have seen above, localized states in the vicinity of the Fermi energy are the most useful for transport at low temperatures. Therefore the Coulomb gap essentially modifies the temperature dependence of the hopping conductivity in the VRH regime at low temperatures. The formal analysis of the T -dependence of the conductivity in the presence of the Coulomb gap is similar to that for the Mott's law discussed above. Using the parabolic energy dependence of the DOS function, one arrives at the result

$$\sigma = \sigma_0 \exp \left[- \left(\frac{\tilde{T}_0}{T} \right)^{1/2} \right] \quad (9.36)$$

with $\tilde{T}_0 = \tilde{\beta} e^2 / (\kappa \alpha k_B)$, where $\tilde{\beta}$ is a numerical coefficient.

Equations (9.33) and (9.36) belong to the most famous theoretical results in the field of variable-range hopping conduction. However these formulae are usually of little help to researchers working with essentially noncrystalline materials, such as amorphous, vitreous or organic semiconductors. The reason is as follows. The above formulae were derived for the cases of either constant DOS (9.33) or a parabolic DOS (9.36) in the energy range associated with hopping conduction. These conditions can usually be met in the impurity band of a lightly doped crystalline semiconductor. In the most disordered materials, however, the energy distribution of the localized states is described by a DOS function that is very strongly energy-dependent. In amorphous, vitreous and microcrystalline semiconductors, the energy dependence of the DOS function is believed to be expo-

ponential, while in organic materials it is usually assumed to be Gaussian. In these cases, new concepts are needed in order to describe the hopping conduction. In the next section we present these new concepts and calculate the way the conductivity depends on temperature and on the concentration of localized states in various significantly noncrystalline materials.

9.3.3 Description of Charge-Carrier Energy Relaxation and Hopping Conduction in Inorganic Noncrystalline Materials

In most inorganic noncrystalline materials, such as vitreous, amorphous and polycrystalline semiconductors, the localized states for electrons are distributed over a rather broad energy range with a width of the order of an electronvolt. The DOS function that describes this energy distribution in such systems is believed to have a purely exponential shape

$$g(\varepsilon) = \frac{N_0}{\varepsilon_0} \exp \left(- \frac{\varepsilon}{\varepsilon_0} \right), \quad (9.37)$$

where the energy ε is counted positive from the mobility edge towards the center of the mobility gap, N_0 is the total concentration of localized states in the band tail, and ε_0 determines the energy scale of the tail. To be precise, we consider that electrons are the charge carriers here. The result for holes can be obtained in an analogous way. Values of ε_0 in inorganic noncrystalline materials are believed to vary between 0.025 eV and 0.05 eV, depending on the system under consideration.

It is worth noting that arguments in favor of a purely exponential shape for the DOS in the band tails of inorganic noncrystalline materials described by (9.37) cannot be considered to be well justified. They are usually based on a rather ambiguous interpretation of experimental data. One of the strongest arguments in favor of (9.37) is the experimental observation of the exponential decay of the light absorption coefficient for photons with an energy deficit ε with respect to the energy width of the mobility gap (see, for example, *Mott and Davis* [9.32]). One should mention that this argument is valid only under the assumption that the energy dependence of the absorption coefficient is determined solely by the energy dependence of the DOS. However, in many cases the matrix element for electron excitation by a photon in noncrystalline materials also strongly depends on energy [9.14, 37]. Hence any argument for the shape of the DOS based on the energy dependence of the light absorption coefficient should be taken very cautiously. Another argument in favor of (9.37) comes

Fig. 9.10 Schematic view of the Coulomb gap. The insert shows the parabolic shape of the DOS near the Fermi level

from the measurements of dispersive transport in time-of-flight experiments. In order to interpret the observed time dependence of the mobility of charge carriers, one usually assumes that the DOS for the band tail takes the form of (9.37) (see, for example, *Orenstein and Kastner* [9.38]). One of the main reasons for such an assumption is probably the ability to solve the problem analytically without elaborate computer work.

In the following we start our consideration of the problem by also assuming that the DOS in a band tail of a noncrystalline material has an energy dependence that is described by (9.37). This simple function will allow us to introduce some valuable concepts that have been developed to describe dynamic effects in noncrystalline materials in the most transparent analytical form. We first present the concept of the so-called transport energy, which, in our view, provides the most transparent description of the charge transport and energy relaxation of electrons in noncrystalline materials.

The Concept of the Transport Energy

The crucial role of a particular energy level in the hopping transport of electrons via localized band-tail states with the DOS described by (9.37) was first recognized by *Grünewald and Thomas* [9.39] in their numerical analysis of equilibrium variable-range hopping conductivity. This problem was later considered by *Shapiro and Adler* [9.40], who came to the same conclusion as *Grünewald and Thomas*, namely that the vicinity of one particular energy level dominates the hopping transport of electrons in the band tails. In addition, they achieved an analytical formula for this level and showed that its position does not depend on the Fermi energy.

Independently, the rather different problem of nonequilibrium energy relaxation of electrons by hopping through the band tail with the DOS described by (9.37) was solved at the same time by *Monroe* [9.41]. He showed that, starting from the mobility edge, an electron most likely makes a series of hops downward in energy. The manner of the relaxation process changes at some particular energy ε_t , which Monroe called the transport energy (TE). The hopping process near and below TE resembles a multiple-trapping type of relaxation, with the TE playing a role similar to the mobility edge. In the multiple-trapping relaxation process [9.38], only electron transitions between delocalized states above the mobility edge and the localized band-tail states are allowed, while hopping transitions between the localized tail states are neglected. Hence, every second transition brings the electron to the mobility edge. The TE of *Monroe* [9.41] coincides exactly with the energy

level discovered by *Grünewald and Thomas* [9.39] and by *Shapiro and Adler* [9.40] for equilibrium hopping transport.

Shklovskii et al. [9.42] have shown that the same energy level ε_t also determines the recombination and transport of electrons in the nonequilibrium steady state under continuous photogeneration in a system with the DOS described by (9.37).

It is clear, then, that the TE determines both equilibrium and nonequilibrium and both transient and steady-state transport phenomena. The question then arises as to why this energy level is so universal that electron hopping in its vicinity dominates all transport phenomena. Below we derive the TE by considering a single hopping event for an electron localized deep in the band tail. It is the transport energy that maximizes the hopping rate as a final electron energy in the hop, independent of its initial energy [9.43]. All derivations below are carried out for the case $k_B T < \varepsilon_0$.

Consider an electron in a tail state with energy ε_i . According to (9.24), the typical rate of downward hopping of such an electron to a neighboring localized state deeper in the tail with energy $\varepsilon_j \geq \varepsilon_i$ is

$$v_{\downarrow}(\varepsilon_i) = v_0 \exp\left(-\frac{2r(\varepsilon_i)}{\alpha}\right), \quad (9.38)$$

where

$$r(\varepsilon) \approx \left[\frac{4\pi}{3} \int_{\varepsilon_i}^{\infty} g(x) dx \right]^{-1/3}. \quad (9.39)$$

The typical rate of upward hopping for such an electron to a state less deep in the tail with energy $\varepsilon_j \leq \varepsilon_i$ is

$$v_{\uparrow}(\varepsilon_i, \delta) = v_0 \exp\left[-\frac{2r(\varepsilon_i - \delta)}{\alpha} - \frac{\delta}{k_B T}\right], \quad (9.40)$$

where $\delta = \varepsilon_i - \varepsilon_j \geq 0$. This expression is not exact. The average nearest-neighbor distance, $r(\varepsilon_i - \delta)$, is based on all states deeper than $\varepsilon_i - \delta$. For the exponential tail, this is equivalent to considering a slice of energy with a width of the order ε_0 . This works for a DOS that varies slowly compared with $k_B T$, but not in general. It is also assumed for simplicity that the localization length, α , does not depend on energy. The latter assumption can be easily jettisoned at the cost of somewhat more complicated forms of the following equations.

We will analyze these hopping rates at a given temperature T , and try to find the energy difference δ that provides the fastest typical hopping rate for an electron placed initially at energy ε_i . The corresponding energy

difference, δ , is determined by the condition

$$\frac{d\nu_{\uparrow}(\varepsilon_i, \delta)}{d\delta} = 0. \quad (9.41)$$

Using (9.37), (9.39) and (9.40), we find that the hopping rate in (9.40) has its maximum at

$$\delta = \varepsilon_i - 3\varepsilon_0 \ln \frac{3\varepsilon_0(4\pi/3)^{1/3} N_0^{1/3} \alpha}{2k_B T}. \quad (9.42)$$

The second term in the right-hand side of (9.42) is called the transport energy ε_t after *Monroe* [9.41]:

$$\varepsilon_t = 3\varepsilon_0 \ln \frac{3\varepsilon_0(4\pi/3)^{1/3} N_0^{1/3} \alpha}{2k_B T}. \quad (9.43)$$

We see from (9.42) that the fastest hop occurs to the state in the vicinity of the TE, independent of the initial energy ε_i , provided that ε_i is deeper in the tail than ε_t ; in other words, if $\delta \geq 0$. This result coincides with that of *Monroe* [9.41]. At low temperatures, the TE ε_t is situated deep in the band tail, and as the temperature rises it moves upward towards the mobility edge. At some temperature T_c , the TE merges with the mobility edge. At higher temperatures, $T > T_c$, the hopping exchange of electrons between localized band tail states becomes inefficient and the dynamic behavior of electrons is described by the well-known multiple-trapping model (see, for instance, *Orenstein and Kastner* [9.38]). At low temperatures, $T < T_c$, the TE replaces the mobility edge in the multiple-trapping process [9.41], as shown in Fig. 9.11. The width, W , of the maximum of the hopping rate is determined by the requirement that near ε_t the hopping rate, $\nu_{\uparrow}(\varepsilon_i, \delta)$, differs by less than a factor of e from the value $\nu_{\uparrow}(\varepsilon_t, \varepsilon_t - \varepsilon_t)$. One finds [9.42]

$$W = \sqrt{6\varepsilon_0 k_B T}. \quad (9.44)$$

For shallow states with $\varepsilon_i \leq \varepsilon_t$, the fastest hop (on average) is a downward hop to the nearest spatially localized state in the band tail, with the rate determined by (9.38) and (9.39). We recall that the energies of electron states are counted positive downward from the mobility edge towards the center of the mobility gap. This means that electrons in the shallow states with $\varepsilon_i \leq \varepsilon_t$ normally hop into deeper states with $\varepsilon > \varepsilon_t$, whereas electrons in the deep states with $\varepsilon_i > \varepsilon_t$ usually hop upward in energy into states near ε_t in the energy interval W , determined by (9.44).

This shows that ε_t must play a crucial role in those phenomena, which are determined by electron hopping in the band tails. This is indeed the case, as shown in numerous review articles where comprehensive theories based on the concept of the TE can be found (see,

Fig. 9.11 Hopping path via the transport energy. In the left frame, the exponential DOS is shown schematically. The right frame depicts the transport path constructed from upward and downward hops. The upward transitions bring the charge carrier to sites with energies close to the transport energy ε_t

for instance, *Shklovskii et al.* [9.42]). We will consider only one phenomenon here for illustration, namely the hopping energy relaxation of electrons in a system with the DOS described by (9.37). This problem was studied initially by *Monroe* [9.41].

Consider an electron in some localized shallow energy state close to the mobility edge. Let the temperature be low, $T < T_c$, so that the TE, ε_t , lies well below the mobility edge, which has been chosen here as a reference energy, $\varepsilon = 0$. The aim is to find the typical energy, $\varepsilon_d(t)$, of our electron as a function of time, t . At early times, as long as $\varepsilon_d(t) < \varepsilon_t$, the relaxation is governed by (9.38) and (9.39). The depth $\varepsilon_d(t)$ of an electron in the band tail is determined by the condition

$$\nu_{\downarrow}[\varepsilon_d(t)] t \approx 1. \quad (9.45)$$

This leads to the double logarithmical dependence $\varepsilon_d(t) \propto \varepsilon_0 \ln[\ln(\nu_0 t)] + C$, where constant C depends on $\varepsilon_0, N_0, \alpha$ in line with (9.38) and (9.39). Indeed, (9.38) and (9.45) prescribe the logarithmic form of the time dependence of the hopping distance, $r(t)$, and (9.37) and (9.39) then lead to another logarithmic dependence $\varepsilon_d[r(t)]$ [9.41]. At the time

$$t_c \approx \nu_0^{-1} \exp\left(\frac{3\varepsilon_0}{k_B T}\right) \quad (9.46)$$

the typical electron energy, $\varepsilon_d(t)$, approaches the TE ε_t , and the style of the relaxation process changes. At $t > t_c$, every second hop brings the electron into states in the vicinity of the TE ε_t from where it falls downward in

energy to the nearest (in space) localization site. In the latter relaxation process, the typical electron energy is determined by the condition [9.41]

$$\nu_{\uparrow}[\varepsilon_d(t), \varepsilon_t] t \approx 1, \quad (9.47)$$

where $\nu_{\uparrow}[\varepsilon_d(t), \varepsilon_t]$ is the typical rate of electron hopping upward in energy toward the TE [9.41]. This condition leads to a typical energy position of the relaxing electron at time t of

$$\varepsilon_d(t) \approx 3\varepsilon_0 \ln[\ln(\nu_0 t)] - \varepsilon_0 \left[8 / (N_0 \alpha^3) \right]. \quad (9.48)$$

This is a very important result, which shows that in a system where the DOS has a pure exponential energy dependence, described by (9.37), the typical energy of a set of independently relaxing electrons would drop deeper and deeper into the mobility gap with time. This result is valid as long as the electrons do not interact with each other, meaning that the occupation probabilities of the electron energy levels are not taken into account. This condition is usually met in experimental studies of transient processes, in which electrons are excited by short (in time) pulses, which are typical of time-of-flight studies of the electron mobility in various disordered materials. In this case, only a small number of electrons are present in the band tail states. Taking into account the huge number of localized band tail states in most disordered materials, one can assume that most of the states are empty and so the above formulae for the hopping rates and electron energies can be used. In this case the electron mobility is a time-dependent quantity [9.41]. A transport regime in which mobility of charge carriers is time-dependent is usually called dispersive transport (see, for example, *Mott and Davis* [9.32], *Orenstein and Kastner* [9.38], *Monroe* [9.41]). Hence we have to conclude that the transient electron mobility in inorganic noncrystalline materials with the DOS in the band tails as described by (9.37) is a time-dependent quantity and the transient electrical conductivity has dispersive character. This is due to the nonequilibrium behavior of the charge carriers. They continuously drop in energy during the course of the relaxation process.

In some theoretical studies based on the Fokker–Planck equation it has been claimed that the maximum of the energy distribution of electrons coincides with the TE ε_t and hence it is independent of time. This statement contradicts the above result where the maximum of the distribution is at energy $\varepsilon_d(t)$, given by (9.48). The Fokker–Planck approach presumes the diffusion of

charge carriers over energy. Hence it is invalid for describing the energy relaxation in the exponential tails, in which electron can move over the full energy width of the DOS (from a very deep energy state toward the TE) in a single hopping event.

In the equilibrium conditions, when electrons in the band tail states are provided by thermal excitation from the Fermi energy, a description of the electrical conductivity can easily be derived using (9.5)–(9.7) [9.39]. The maximal contribution to the integral in (9.5) comes from the electrons with energies in the vicinity of the TE ε_t , in an energy range with a width, W , described by (9.44). Neglecting the temperature dependence of the pre-exponential factor, σ_0 , one arrives at the temperature dependence of the conductivity:

$$\sigma \approx \sigma_0 \exp \left(-\frac{2r(\varepsilon_t)}{B_c^{-1/3} \alpha} - \frac{\varepsilon_F - \varepsilon_t}{k_B T} \right), \quad (9.49)$$

where coefficient $B_c \approx 2.7$ is inserted in order to take into account the need for a charge carrier to move over macroscopic percolation distances in order to provide low-frequency charge transport.

A very similar theory is valid for charge transport in noncrystalline materials under stationary excitation of electrons (for example by light) [9.42]. In such a case, one first needs to develop a theory for the steady state of the system under stationary excitation. This theory takes into account various recombination processes for charge carriers and provides their stationary concentration along with the position of the quasi-Fermi energy. After solving this recombination problem, one can follow the track of the theory of charge transport in quasi-thermal equilibrium [9.39] and obtain the conductivity in a form similar to (9.49), where ε_F is the position of the quasi-Fermi level. We skip the corresponding (rather sophisticated) formulae here. Interested readers can find a comprehensive description of this sort of theory for electrical conductivity in the literature (see, for instance, *Shklovskii et al.* [9.42]).

Instead, in the next section we will consider a very interesting problem related to the nonequilibrium energy relaxation of charge carriers in the band tail states. It is well known that at low temperatures, $T \leq 50$ K, the photoconductivities of various inorganic noncrystalline materials, such as amorphous and microcrystalline semiconductors, do not depend on temperature [9.44–46]. At low temperatures, the TE ε_t lies very deep in the band tail and most electrons hop downward in energy, as described by (9.38) and (9.39). In such a regime, the

photoconductivity is a temperature-independent quantity determined by the loss of energy during the hopping of electrons via the band-tail states [9.47]. During this hopping relaxation, neither the diffusion coefficient D nor the mobility of the carriers μ depend on temperature, and the conventional form of Einstein's relationship $\mu = eD/k_B T$ cannot be valid. The question then arises as to what the relation between μ and D is for hopping relaxation. We answer this question in the following section.

Einstein's Relationship for Hopping Electrons

Let us start by considering a system of nonequilibrium electrons in the band tail states at $T = 0$. The only process that can happen with an electron is its hop downward in energy (upward hops are not possible at $T = 0$) to the nearest localized state in the tail. Such a process is described by (9.37)–(9.39). If the spatial distribution of localized tail states is isotropic, the probability of finding the nearest neighbor is also isotropic in the absence of the external electric field. In this case, the process of the hopping relaxation of electrons resembles diffusion in space. However, the median length of a hop (the distance r to the nearest available neighbor), as well as the median time, $\tau = v_{\downarrow}^{-1}(r)$, of a hop [see (9.38)] increases during the course of relaxation, since the hopping process brings electrons deeper into the tail. Nevertheless, one can ascribe a diffusion coefficient to such a process [9.42]:

$$D(r) = \frac{1}{6} v_{\downarrow}(r) r^2. \quad (9.50)$$

Here $v_{\downarrow}(r)r^2$ replaces the product of the “mean free path” r and the “velocity” $r \cdot v_{\downarrow}(r)$, and the coefficient $1/6$ accounts for the spatial symmetry of the problem. According to (9.37)–(9.39) and (9.50), this diffusion coefficient decreases exponentially with increasing r and hence with the number of successive electron hops in the relaxation process.

In order to calculate the mobility of electrons during hopping relaxation under the influence of the electric field, one should take into account the spatial asymmetry of the hopping process due to the field [9.47, 48]. Let us consider an electron in a localized state at energy ε . If an external electric field with a strength F is applied along direction x , the concentration of tail states available to this hopping electron at $T = 0$ (in other words those that have energies deeper in the tail than ε) is [9.47]

$$N(\varepsilon, x) = N(\varepsilon) \left(1 + \frac{eFx}{\varepsilon_0} \right), \quad (9.51)$$

where

$$N(\varepsilon) = \int_{\varepsilon}^{\infty} g(\varepsilon) d\varepsilon = N_0 \exp \left(-\frac{\varepsilon}{\varepsilon_0} \right). \quad (9.52)$$

It was assumed in the derivation of (9.51) that $eFx \ll \varepsilon_0$.

Due to the exponential dependence of the hopping rate on the hopping length r , the electron predominantly hops to the nearest tail state among the available states if $r \gg \alpha$, which we assume to be valid. Let us calculate the average projection $\langle x \rangle$ on the field direction of the vector \mathbf{r} from the initial states at energy ε to the nearest available neighbor among sites with a concentration $N(\varepsilon, x)$ determined by (9.51). Introducing spherical coordinates with the angle θ between r and the x -axis, we obtain [9.48]

$$\begin{aligned} \langle x \rangle &= \int_0^{2\pi} d\phi \int_0^{\pi} d\theta \sin \theta \\ &\times \int_0^{\infty} [dr \cdot r^3 \cos(\theta) \cdot N(\varepsilon, r \cos \theta)] \\ &\times \exp \left[-\int_0^{2\pi} d\phi \int_0^{\pi} d\theta \sin \theta \right. \\ &\times \left. \int_0^r dr' r'^2 N(\varepsilon, r' \cos \theta) \right]. \end{aligned} \quad (9.53)$$

Substituting (9.51) for $N(\varepsilon, r \cos \theta)$, calculating the integrals in (9.53) and omitting the second-order terms

$$\left(\frac{eN^{-1/3}(\varepsilon)F}{\varepsilon_0} \right)^2 \ll 1, \quad (9.54)$$

we obtain

$$\langle x \rangle = \frac{eFN^{-2/3}(\varepsilon)}{3\varepsilon_0} \frac{\Gamma(5/3)}{(4\pi/3)^{2/3}}, \quad (9.55)$$

where Γ is the gamma-function and $N(\varepsilon)$ is determined by (9.52). Equation (9.55) gives the average displacement in the field direction of an electron that hops downward from a state at energy ε to the nearest available neighbor in the band tail. The average length $\langle r \rangle$ of

such a hop is

$$\begin{aligned} \langle r \rangle &= \int_0^\infty dr 4\pi r^3 N(\varepsilon) \exp \left[-\frac{4\pi}{3} N(\varepsilon) r^3 \right] \\ &= \left(\frac{4\pi N(\varepsilon)}{3} \right)^{-1/3} \Gamma \left(\frac{4}{3} \right). \end{aligned} \quad (9.56)$$

One can ascribe to the hopping process a mobility

$$\begin{aligned} \mu &= \frac{v}{F} = \frac{\langle x \rangle v(\langle r \rangle)}{F} \\ &= \frac{e N^{-2/3}(\varepsilon) v(\langle r \rangle)}{3\varepsilon_0} \frac{\Gamma(5/3)}{(4\pi/3)^{2/3}} \end{aligned} \quad (9.57)$$

and a diffusion coefficient

$$\begin{aligned} D &= \frac{1}{6} \langle r \rangle^2 v(\langle r \rangle) \\ &= \frac{1}{6} N^{-2/3}(\varepsilon) v(\langle r \rangle) \frac{\Gamma^2(4/3)}{(4\pi/3)^{2/3}}. \end{aligned} \quad (9.58)$$

Expressions (9.57) and (9.58) lead to a relationship between μ and D of the form

$$\mu = \frac{2\Gamma(5/3)}{\Gamma^2(4/3)} \frac{e}{\varepsilon_0} D \approx 2.3 \frac{e}{\varepsilon_0} D. \quad (9.59)$$

This formula replaces the Einstein's relationship $\mu = eD/k_B T$ for electron hopping relaxation in the exponential band tail. Several points should be noted about this result. First of all, one should clearly realize that (9.59) is valid for nonequilibrium energy-loss relaxation in which only downward (in energy) transitions between localized states can occur. This regime is valid only at low temperatures when the TE ε_t is very deep in the band tail. As the temperature increases, the upward hops become more and more efficient for electron relaxation. Under these circumstances, the relation between μ and D evolves gradually with rising temperature from its temperature-independent form at $T = 0$ to the conventional Einstein's relationship, $\mu = eD/k_B T$ [9.50, 51]. Secondly, one should realize that (9.59) was derived in the linear regime with respect to the applied field under the assumption that $eFx \ll \varepsilon_0$. According to (9.55), the quantity $\langle x \rangle$ is proportional to $N^{-2/3}(\varepsilon) = N_0^{-2/3} \exp [2\varepsilon/(3\varepsilon_0)]$, in other words it increases exponentially during the course of the relaxation toward larger localization energies ε . This means that for deep localized states in the band tail, the condition $eFx \ll \varepsilon_0$ breaks down. The boundary energy for application of the linear theory depends on the strength of the electric field, F . As F decreases, this boundary energy

drops deeper into the tail. However, for any F , there is always a boundary energy in the tail below which the condition $eFx \ll \varepsilon_0$ cannot be fulfilled and where nonlinear effects play the decisive role in the hopping conduction of charge carriers. In the next section we show how one can describe these nonlinear effects with respect to the applied electric field.

Nonlinear Effects in Hopping Conduction

Transport phenomena in inorganic noncrystalline materials, such as amorphous semiconductors, under the influence of high electric fields are the foci for intensive experimental and theoretical study. This is due to observations of strong nonlinearities in the dependencies of the dark conductivity [9.11, 52, 53], the photoconductivity [9.49] and the charge carrier drift mobility [9.54–56] on the field for high electric fields. These effects are most pronounced at low temperatures, when charge transport is determined by electron hopping via localized band tail states (Fig. 9.12).

Whereas the field-dependent hopping conductivity at low temperatures has always been a challenge to describe theoretically, theories for the temperature dependence of the hopping conductivity in low electric fields have been successfully developed for all of the transport regimes discussed: for the dark conductivity [9.39], for the drift mobility [9.41], and for the photoconductivity [9.42]. In all of these theories, hopping transitions of electrons between localized states in the exponential band tails play a decisive role, as described above in (9.37)–(9.59).

Fig. 9.12 Dependence of the photoconductivity in a-Si:H on the electric field at different temperatures [9.49]

Shklovskii [9.57] was the first to recognize that a strong electric field plays a similar role to that of temperature in hopping conduction. In order to obtain the field dependence of the conductivity $\sigma(F)$ at high fields, *Shklovskii* [9.57] replaced the temperature T in the well-known dependence $\sigma(T)$ for low fields by a function $T_{\text{eff}}(F)$ of the form

$$T_{\text{eff}} = \frac{eF\alpha}{2k_B}, \quad (9.60)$$

where e is the elementary charge, k_B is the Boltzmann constant, and α is the localization length of electrons in the band tail states. A very similar result was obtained later by *Grünwald* and *Movaghar* [9.58] in their study of the hopping energy relaxation of electrons through band tails at very low temperatures and high electric fields. The same idea was also used by *Shklovskii* et al. [9.42], who suggested that, at $T = 0$, one can calculate the field dependence of the stationary photoconductivity in amorphous semiconductors by replacing the laboratory temperature T in the formulae of the low-field finite-temperature theory by an effective temperature $T_{\text{eff}}(F)$ given by (9.60).

It is easy to understand why the electric field plays a role similar to that of temperature in the energy relaxation of electrons. Indeed, in the presence of the field, the number of sites available at $T = 0$ is significantly enhanced in the field direction, as shown in Fig. 9.13. Hence electrons can relax faster at higher fields. From the figure it is apparent that an electron can increase its energy with respect to the mobility edge by an amount $\varepsilon = eFx$ in a hopping event over a distance x in the direction prescribed by the electric field. The process is reminiscent of thermal activation. The analogy becomes tighter when we express the transition rate for this hop as

$$\begin{aligned} \nu &= \nu_0 \exp\left(-\frac{2x}{\alpha}\right) = \nu_0 \exp\left(-\frac{2\varepsilon}{eF\alpha}\right) \\ &= \nu_0 \exp\left(-\frac{\varepsilon}{k_B T_{\text{eff}}(F)}\right), \end{aligned} \quad (9.61)$$

where $T_{\text{eff}}(F)$ is provided by (9.60).

This electric field-induced activation at $T = 0$ produces a Boltzmann tail to the energy distribution function of electrons in localized states as shown by numerical calculations [9.59, 60]. In Fig. 9.12, the field-dependent photoconductivity in a-Si:H is shown for several temperatures [9.49]. If we compare the photoconductivity at the lowest measured temperature,

Fig. 9.13 Tunneling transition of a charge carrier in the band tail that is affected by a strong electric field. Upon traveling the distance x , the carrier acquires the energy eFx , where F is the strength of the electric field, and e is the elementary charge

$T = 20$ K in Fig. 9.12, with the low-field photoconductivity at $T = T_{\text{eff}} = \frac{eF\alpha}{2k_B}$ as measured by *Hoheisel* et al. [9.44] and by *Stradins* and *Fritzsche* [9.45], we come to the conclusion that the data agree quantitatively if one assumes that the localization length $\alpha = 1.05$ nm [9.42], which is very close to the value $\alpha \approx 1.0$ nm found for a-Si:H from independent estimates [9.11]. This comparison shows that the concept of the effective temperature based on (9.60) provides a powerful tool for estimating transport coefficient non-linearity with respect to the electric field using the low-field results for the temperature dependencies of such coefficients.

However, experiments are usually carried out not at $T = 0$ but at finite temperatures, and so the question of how to describe transport phenomena in the presence of both factors, finite T and high F , arises. By studying the steady state energy distribution of electrons in numerical calculations and computer simulations [9.59, 60], as well as straightforward computer simulations of the steady-state hopping conductivity and the transient energy relaxation of electrons [9.61], the following result was found. The whole set of transport coefficients can be represented by a function with a single parameter $T_{\text{eff}}(F, T)$

$$T_{\text{eff}}(F, T) = \left[T^\beta + \left(\gamma \frac{eF\alpha}{k_B} \right)^\beta \right]^{1/\beta}, \quad (9.62)$$

where $\beta \approx 2$ and γ is between 0.5 and 0.9 depending on which transport coefficient is considered [9.61]. We

are aware of no analytical theory that can support this numerical result.

To wrap up this section we would like to make the following remark. It is commonly claimed in the scientific literature that transport coefficients in the hopping regime should have a purely exponential dependence on the applied electric field. The idea behind such statements seems rather transparent. Electric field diminishes potential barriers between localized states by an amount $\Delta\varepsilon = eFx$, where x is the projection of the hopping radius on the field direction. The field should therefore diminish the activation energies in (9.24) and (9.25) by this amount, leading to the term $\exp(eFx/k_B T)$ in the expressions for the charge carrier mobility, diffusivity and conductivity. One should, however, take into account that hopping transport in all real materials is essentially described by the variable-range hopping process. In such a process, as discussed above, the interplay between spatial and energy-dependent terms in the exponents of the transition probabilities determine the conduction path. Therefore it is not enough to solely take into account the influence of the strong electric field on the activation energies of single hopping transitions. One should consider the modification of the whole transport path due to the effect of the strong field. It is this **VRH** nature of the hopping process that leads to a more complicated field dependence for the transport coefficients expressed by (9.60)–(9.62).

We have now completed our description of electron transport in inorganic disordered materials with exponential **DOS** in the band tails. In the next section we tackle the problem of charge transport in organic disordered materials.

9.3.4 Description of Charge Carrier Energy Relaxation and Hopping Conduction in Organic Noncrystalline Materials

Electron transport and energy relaxation in disordered organic solids, such as molecularly doped polymers, conjugated polymers and organic glasses, has been the subject of intensive experimental and theoretical study for more than 20 years. Although there is a wide array of different disordered organic solids, the charge transport process is similar in most of these materials. Even at the beginning of the 1980s it was well understood that the main transport mechanism in disordered organic media is the hopping of charge carriers via spatially randomly distributed localized states. Binary systems like doped polymeric matrices provide canonical examples of disordered organic materials that exhibit

the hopping transport mechanism. Examples include polyvinylcarbazole (**PVK**) or bis-polycarbonate (**Lexan**) doped with either strong electron acceptors such as trinitrofluorenone acting as an electron transporting agent, or strong electron donors such as derivatives of triphenylamine of triphenylmethane for hole transport [9.62, 63]. To avoid the need to specify whether transport is carried by electrons or holes each time, we will use a general notation of “charge carrier” below. The results are valid for both types of carrier – electrons or holes. Charge carriers in disordered organic materials are believed to be strongly localized [9.18, 62–64]. The localization centers are molecules or molecular subunits, henceforth called sites. These sites are located in statistically different environments. As a consequence, the site energies, which are to great extent determined by electronic polarization, fluctuate from site to site. The fluctuations are typically on the order of 0.1 eV [9.65]. This is about one order of magnitude larger than the corresponding transfer integrals [9.65]. Therefore carrier wavefunctions can be considered to be strongly localized [9.65].

As discussed above, the crucial problem when developing a theoretical picture for hopping transport is the structure of the energy spectrum of localized states, **DOS**. It is believed that, unlike inorganic noncrystalline materials where the **DOS** is believed exponential, the energy dependence of the **DOS** in organic disordered solids is Gaussian (see *Bässler* [9.18] and references therein),

$$g(\varepsilon) = \frac{N_0}{\varepsilon_0 \sqrt{2\pi}} \exp\left(-\frac{\varepsilon^2}{2\varepsilon_0^2}\right), \quad (9.63)$$

where N_0 is the total concentration of states and ε_0 is the energy scale of the **DOS**. The strongest evidence in favor of such an energy spectrum in disordered organic materials is the ability to reproduce the observed experimentally temperature dependence of the carrier mobility and that of hopping conductivity assuming the Gaussian **DOS** in computer simulations [9.18, 66]. It has been observed in numerous experimental studies [9.67–73] that the temperature dependence of the drift mobility of charge carriers in disordered organic solids takes the form

$$\mu \propto \exp\left[-\left(\frac{T_0}{T}\right)^2\right] \quad (9.64)$$

with a characteristic temperature T_0 , as shown in Fig. 9.14a. Computer simulations and theoretical calculations [9.65, 66, 74, 75] with the Gaussian **DOS**

described by (9.63) give a dependence of the form

$$\mu \propto \exp \left[- \left(C \frac{\varepsilon_0}{k_B T} \right)^2 \right], \quad (9.65)$$

where C is a numerical coefficient. Computer simulations [9.65, 66] give a value $C \approx 0.69$ for this coefficient, and analytical calculations [9.74, 75] predict a similar value of $C \approx 0.64$. Equation (9.65) is often used to determine the parameter ε_0 of the DOS from experimental measurements of the $\ln(\mu)$ versus $(1/T)^2$ dependences (see, for example, Ochse et al. [9.71]).

One may wonder whether the theoretical description of hopping conduction and carrier energy relaxation in a system with a Gaussian DOS (9.63) should differ significantly from the theory described above for disordered

systems with a purely exponential DOS (9.37). The answer to this question is yes. The reason becomes clear if one considers the behavior of a single charge carrier in an empty system. In an empty system with an exponential DOS, a charge carrier always (on average) falls downward in energy if $k_B T < \varepsilon_0$ [see (9.45)–(9.48)], and its mobility continuously decreases with time; however, in a system with a Gaussian DOS, a particular energy level ε_∞ determines the equilibrium energy position of a charge carrier. When it is located at some site with high energy in the Gaussian DOS, the charge carrier first hops via localized states so that its average energy $\varepsilon_d(t)$ decreases until it achieves the energy level ε_∞ after some typical time period τ_{rel} . At times $t < \tau_{\text{rel}}$ the behavior of the carrier qualitatively resembles that seen for the purely exponential DOS. The downward hops are then replaced by relaxation hops that send the carrier upward to the transport energy, and the carrier mobility at $t < \tau_{\text{rel}}$ decreases with time. However, in contrast with the case for the exponential DOS, in a Gaussian DOS the carrier mobility becomes time-independent after a time τ_{rel} , when the average carrier energy reaches the level ε_∞ . At $t > \tau_{\text{rel}}$, the dispersive transport regime with time-dependent carrier mobility is replaced by a quasi-equilibrium so-called “Gaussian transport” regime, in which the spatial spreading of the carrier packet with time can be described by the traditional diffusion picture with a time-independent diffusion coefficient.

The peculiarity of the hopping energy relaxation of charge carriers in a system with a Gaussian DOS described above makes it easier to describe charge transport at times $t > \tau_{\text{rel}}$ than in the case of the exponential DOS. In the latter case, only the presence of a significant number of carriers in a quasi Fermi level can make kinetic coefficients such as mobility, diffusivity and conductivity time-independent and hence conventionally measurable and discussible quantities. In the case of the Gaussian DOS, these kinetic coefficients are not time-dependent at times $t > \tau_{\text{rel}}$. Moreover, in diluted systems one can calculate these coefficients by considering the behavior of a single charge carrier. This makes theoretical considerations of electrical conductivity in organic disordered solids with a Gaussian DOS much easier than when considering inorganic noncrystalline materials with an exponential DOS. Let us now calculate ε_∞ , τ_{rel} and μ in disordered organic solids with a Gaussian DOS.

Computer simulations [9.66] and analytical calculations [9.74, 75] show that the mean energy of the independently hopping carriers, initially distributed randomly over all states in the Gaussian DOS, decreases

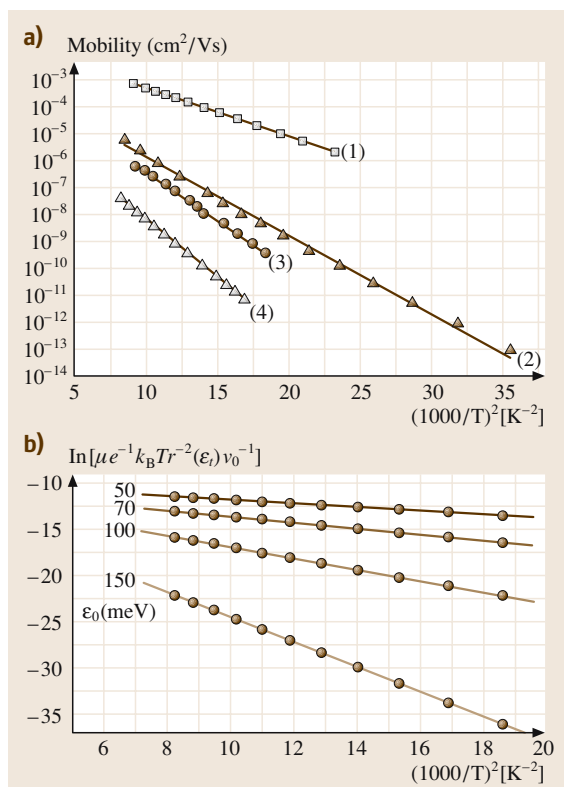

Fig. 9.14a,b Temperature dependence of the zero-field mobility in organic semiconductors. Experimental data (a): (1) di-*p*-tolylphenylamine containing (DEASP)-traps [9.69]; (2) (BD)-doped polycarbonate [9.70]; (3) (NTDI)-doped poly(styrene) [9.68]; (4) (BD)-doped TTA/polycarbonate [9.72]. Theoretical results (b) were obtained via (9.73)

with time until it approaches the thermal equilibrium value

$$\varepsilon_\infty = \frac{\int_{-\infty}^{\infty} \varepsilon \exp\left(-\frac{\varepsilon}{k_B T}\right) g(\varepsilon) d\varepsilon}{\int_{-\infty}^{\infty} \exp\left(-\frac{\varepsilon}{k_B T}\right) g(\varepsilon) d\varepsilon} = -\frac{\varepsilon_0^2}{k_B T}. \quad (9.66)$$

The time τ_{rel} required to reach this equilibrium is of key importance in the analysis of experimental data [9.65], since at $t < \tau_{\text{rel}}$ the carrier mobility decreases with time (dispersive transport) until it reaches its equilibrium, time-independent value at $t \approx \tau_{\text{rel}}$. It has been established by computer simulations that τ_{rel} strongly depends on temperature [9.18]:

$$\tau_{\text{rel}} \propto \exp\left[\left(B \frac{\varepsilon_0}{k_B T}\right)^2\right] \quad (9.67)$$

with $B \approx 1.07$. Given that the same hopping processes determine both μ and τ_{rel} , researchers were puzzled for many years by the fact that they had different coefficients B and C (in other words they have different temperature dependencies) [9.65]. Below we show how to calculate both quantities – μ and τ_{rel} – easily, and we explain their temperature dependencies (obtained experimentally and by computer simulations as expressed by (9.64), (9.65) and (9.67)).

Our theoretical approach is based on the concept of transport energy (TE), introduced in Sect. 9.3.3, where it was calculated for the exponential DOS given by (9.37). Literally repeating these calculations with the Gaussian DOS, given by (9.63), we obtain the equation [9.76, 77]

$$\exp\left(\frac{x^2}{2}\right) \left[\int_{-\infty}^{\frac{x}{\sqrt{2}}} \exp(-t^2) dt \right]^{4/3} = \left[9(2\pi)^{1/2} N_0 \alpha^3 \right]^{-1/3} \frac{k_B T}{\varepsilon_0}. \quad (9.68)$$

If we denote the solution of (9.68) as $X_t(N_0 \alpha^3, k_B T/\varepsilon_0)$, then the transport energy in the Gaussian DOS is equal to

$$\varepsilon_t = \varepsilon_0 \cdot X_t\left(N_0 \alpha^3, k_B T/\varepsilon_0\right). \quad (9.69)$$

Charge carriers perform thermally activated transitions from states with energies below the TE, ε_t , to the states with energies close to that of the TE [9.76]. Charge carriers hop downward in energy from states with energies

above the TE to the spatially nearest sites with rates determined by (9.38) and (9.39).

Now that we have clarified the relaxation kinetics of charge carriers in the Gaussian DOS, it is easy to calculate the relaxation time τ_{rel} and the drift mobility μ . We consider the case $\varepsilon_\infty < \varepsilon_t < 0$, which corresponds to all reasonable values of material parameters $N_0 \alpha^3$ and $k_B T/\varepsilon_0$ [9.76]. The energy relaxation of most carriers with energies ε in the interval $\varepsilon_\infty < \varepsilon < \varepsilon_t$ occurs via a multiple trapping-like process, well described in the literature (see, for example, *Orenstein and Kastner* [9.38] or *Marschall* [9.78]). Below ε_t the average energy of the carriers $\varepsilon(t)$ moves logarithmically downward with time t . States above $\varepsilon(t)$ achieve thermal equilibrium with states at ε_t at time t , while states below $\varepsilon(t)$ have no chance at time t to exchange carriers with states in the vicinity of ε_t . Hence the occupation of those deep states does not correspond to the equilibrium one, being determined solely by the DOS of the deep states. The system reaches thermal equilibrium when the time-dependent average energy $\varepsilon(t)$ achieves the equilibrium level ε_∞ , determined by (9.66). This happens at $t = \tau_{\text{rel}}$. Since the relaxation of carriers occurs via thermal activation to the level ε_t , the relaxation time τ_{rel} is determined by the time required for activated transitions from the equilibrium level ε_∞ to the transport energy ε_t . Hence, according to (9.40) and (9.47), τ_{rel} is determined by the expression

$$\tau_{\text{rel}} = v_0^{-1} \exp\left[\frac{2r(\varepsilon_t)}{\alpha} + \frac{\varepsilon_t - \varepsilon_\infty}{k_B T}\right]. \quad (9.70)$$

From (9.68)–(9.70) it is obvious that the activation energy of the relaxation time depends on the parameters $N_0 \alpha^3$ and $k_B T/\varepsilon_0$. Hence, generally speaking, this dependence cannot be represented by (9.67) and, if at all, the coefficient B should depend on the magnitude of the parameter $N_0 \alpha^3$. However, numerically solving (9.68)–(9.70) using the value $N_0 \alpha^3 = 0.001$, which was also used in computer simulations by *Bässler* [9.18, 65], confirms the validity of (9.67) with $B \approx 1.0$. This result is in agreement with the value $B \approx 1.07$ obtained from computer simulations [9.18, 65]. A way to describe the temperature dependence of the relaxation time τ_{rel} by (9.67) is provided by the strong temperature dependence of ε_∞ in the exponent in (9.70), while the temperature dependencies of the quantities ε_t and $r(\varepsilon_t)$ in (9.70) are weaker and they almost cancel each other out. However, if $N_0 \alpha^3 = 0.02$, the relaxation time is described by (9.67) with $B \approx 0.9$. This

shows that (9.67) can only be considered to be a good approximation.

Now we turn to the calculation of the carrier drift mobility μ . We assume that the transition time t_{tr} necessary for a carrier to travel through a sample is longer than τ_{rel} , and hence the charge transport takes place under equilibrium conditions. As described above, every second jump brings the carrier upward in energy to the vicinity of ε_t , and is then followed by a jump to the spatially nearest site with deeper energy, determined solely by the DOS. Therefore, in order to calculate the drift mobility μ , we must average the hopping transition times over energy states below ε_t , since only these states are essential to charge transport in thermal equilibrium [9.77, 80]. Hops downward in energy from the level ε_t occur exponentially faster than upward hops towards ε_t . This means that one can neglect the former in the calculation of the average time $\langle t \rangle$. The carrier drift mobility can be evaluated as

$$\mu \approx \frac{e}{k_B T} \frac{r^2(\varepsilon_t)}{\langle t \rangle}, \quad (9.71)$$

where $r(\varepsilon_t)$ is determined via (9.39), (9.63), (9.68) and (9.69). The average hopping time takes the form [9.80]

$$\langle t \rangle = \left[\int_{-\infty}^{\varepsilon_t} g(\varepsilon) d\varepsilon \right]^{-1} \times \int_{-\infty}^{\varepsilon_t} v_0^{-1} g(\varepsilon) \times \exp\left(\frac{2r(\varepsilon_t)B_c^{1/3}}{a} + \frac{\varepsilon_t - \varepsilon}{k_B T}\right) d\varepsilon, \quad (9.72)$$

where $B_c \approx 2.7$ is the percolation parameter. This numerical coefficient is introduced into (9.72) in order to warrant the existence of an infinite percolation path over the states with energies below ε_t . Using (9.63), (9.68), (9.69), (9.71) and (9.72), one obtains the following relation for the exponential terms in the expression for the carrier drift mobility:

$$\begin{aligned} \ln \left[\mu / \left(\frac{er^2(\varepsilon_t)v_0}{k_B T} \right) \right] \\ = -2 \left[\frac{4\sqrt{\pi}}{3B_c} N_0 \alpha^3 \int_{-\infty}^{X_t/\sqrt{\pi}} \exp(-t^2) dt \right]^{-1/3} \\ - \frac{X_t \varepsilon_0}{k_B T} - \frac{1}{2} \left(\frac{\varepsilon_0}{k_B T} \right)^2. \end{aligned} \quad (9.73)$$

It is (9.73) that determines the dependence of the carrier drift mobility on the parameters $N_0 \alpha^3$ and $k_B T/\varepsilon_0$.

Fig. 9.15 Concentration dependence of the drift mobility evaluated from (9.73) (solid line), and the dependence observed experimentally (circles) for TNF/PE and TNF/PVK [9.79]

In Fig. 9.14b, the dependence of the drift mobility on the temperature at $N_0 \alpha^3 = 0.01$ is depicted for several values of ε_0 . The sensitivity of the mobility to temperature is clear from this picture. Comparison of these dependencies with experimental measurements of $\ln(\mu)$ versus $(1/T)^2$ [some are shown in Fig. 9.14a] provides information on the energy scale, ε_0 , of the DOS (see, for example, Bässler [9.18] and Ochse et al. [9.71]).

In Fig. 9.15, the dependence of the drift mobility on $N_0 \alpha^3$ is shown for $k_B T/\varepsilon_0 = 0.3$. Experimental data from Gill [9.81] are also shown in the figure. It is clear that the slope of the mobility exponent as a function of $(N_0 \alpha^3)^{-1/3}$ given by the theory described above agrees with the experimental data. At a very low concentration of localized states, N_0 , when the probability of carrier tunneling in space dominates the transition rate in (9.24), charge carriers hop preferentially to the nearest spatial sites. In this regime of nearest-neighbor hopping, the concentration dependence of the drift mobility is described by (9.28), as illustrated by the dashed line in Fig. 9.15.

So far we have discussed the drift mobility of charge carriers under the assumption that the concentration of charge carriers is much less than that of the localized states in the energy range relevant to hopping transport. In such a case one can assume that the carriers perform independent hopping motion and so the conductivity can be calculated as the product

$$\sigma = en\mu, \quad (9.74)$$

9.4 Concluding Remarks

Beautiful effects have been observed experimentally by studying the charge transport in disordered organic and inorganic materials. Among these, the transport coefficients in the hopping regime show enormously strong dependencies on material parameters. The dependence of the charge carrier mobility on the concentration of localized states N_0 (Fig. 9.15) spreads over many orders of magnitude, as does its dependence on the temperature T (Fig. 9.14) and on the (high) electric field strength F (Fig. 9.12). Such strong variations in physical quantities are typical, say, in astrophysics, but they are not usual in solid state physics. This makes the study of the charge transport in disordered materials absolutely fascinating. The strong dependencies of kinetic coefficients (like drift mobility, diffusivity and conductivity) in disordered materials on various material parameters makes these systems very attractive for various device applications. Since they are relatively inexpensive to manufacture too, it is then easy to understand why disordered organic and inorganic materials are of enormous interest for various technical applications.

These materials also provide a purely academic challenge with respect to their transport phenomena. While traditional kinetic theories developed for crystalline materials are largely dependent on the systems having translational symmetry, there is no such symmetry in disordered materials. However, we have shown in this chapter that it is still possible to develop a reliable theoretical approach to transport phenomena in disordered materials. Particularly interesting is the hopping transport regime. In this regime, charge carriers perform incoherent tunneling jumps between localized states distributed in space and energy. The enormously strong (exponential) dependence of the transition rates on the distances between the sites and their energies call for a completely new set of ideas compared to those for crystalline solids. Conventional transport theories based on the averaging of transition rates lead to ab-

surd results if applied to hopping transport in disordered materials. One can use ideas from percolation theory instead to adequately describe charge transport. One of the most important ideas in this field is so-called variable-range hopping (VRH) conduction. Although the rate of transitions between two localized states is a product of exponential terms that are separately dependent on the concentration of localized states N_0 , the temperature of the system T , and also on the field strength F (for high field strengths), it is generally wrong to assume that the carrier drift mobility, diffusivity or conductivity can also be represented as the product of three functions that are separately dependent on N_0 , T and F . Instead one should search for a percolation path that takes into account the exponential dependences of the hopping rates on all of these parameters simultaneously. Such a procedure, based on strong interplay between the important parameters in the exponents of the transition rates, leads to very interesting and (in some cases) unexpected results, some of which were described in this chapter. For example, it was shown that the effect of a strong electric field on transport coefficients can be accounted for by renormalizing the temperature. Most of the ideas discussed in this chapter were discussed in the early works of Mott and his coauthors (see, for example, *Mott and Davis* [9.32]). Unfortunately, these ideas are not yet known to the majority of researchers working in the field of disordered materials. Moreover, it is often believed that transport phenomena in different disordered materials need to be described using different ideas. Mott based his ideas, in particular the VRH, mostly on inorganic glassy semiconductors. Most of the researchers that are studying amorphous inorganic semiconductors (like a-Si:H) are aware of these ideas. However, new researchers that are working on more modern disordered materials, such as organic disordered solids and dye-sensitized materials, are often not aware of these very useful and powerful ideas developed by Mott and his

followers that can be used to describe charge transport in inorganic disordered systems. In this chapter we have shown that the most pronounced charge transport effects in inorganic and organic disordered materials can be successfully described in a general manner using these ideas.

Although we have presented some useful ideas for describing charge transport in disordered systems above, it is clear that the theoretical side of this field is still embryonic. There are still no reliable theories for charge transport via extended states in disordered materials. Nor are there any reliable theoretical descriptions for the spatial structure of the localized states (DOS) in organic and inorganic noncrystalline materials. All of the theoretical concepts presented in this chapter were developed using very simple models of localization centers with a given energy spectrum that are randomly distributed in

space. No correlations between the spatial positions of the sites and the energies of the electronic states at these sites were considered here. Some theoretical attempts to account for such correlations can be found in the literature, although the correlations have not been calculated ab initio: instead they are inserted into a framework of model assumptions. This shows how far the field of charge transport in disordered materials is from a desirable state. Since these materials are already widely used in various technical applications, such as field transistor manufacture, light-emitting diodes and solar cells, and since the sphere of such applications is increasing, the authors are optimistic about the future of research in this field. The study of fundamental charge transport properties in disordered materials should develop, leading us to a better understanding of the fundamental charge transport mechanisms in such systems.

Dielectric Res

10. Dielectric Response

Nearly all materials are dielectrics, and the measurement of their dielectric response is a very common technique for their characterisation. This chapter is intended to guide scientists and engineers through the subject to the point where they can interpret their data in terms of the microscopic and atomistic dynamics responsible for the dielectric response, and hence derive useful information appropriate to their particular needs. The focus is on the physical concepts underlying the observed behaviour and is developed from material understandable by an undergraduate student. Emphasis is placed on the information content in the data, and the limits to be placed on its interpretation are clearly identified.

Generic forms of behaviour are identified using examples typical of different classes of material, rather than an exhaustive review of the literature. Limited-range charge transport is included as a special item. The theoretical concepts are developed from a basic level up to the ideas current in the field, and the points where these are controversial have been noted so that the

readers can choose for themselves how far to rely on them.

Nearly all materials are dielectrics, that is they do not exhibit a direct-current (DC) conductivity on the macroscopic scale, but instead act as an electrical capacitance i.e. they store charge. The measurement of the dielectric response is noninvasive and has been used for material characterisation throughout most of the 20th century, and consequently a number of books already exist that cover the technique from various points of view. Those that have stood the test of time are *Debye* [10.1], *Smyth* [10.2], *McCrum et al.* [10.3], *Daniels* [10.4], *Bordewijk and Bottcher* [10.5], and *Jonscher* [10.6]. These texts cover the subject in terms of the basic physics [10.1, 5], the material properties [10.2–4], and the electrical features [10.6]. An introduction to the wide range of dielectric response measurements that are undertaken can be obtained by referring to the proceedings

publication of the International Discussion Meeting on Relaxations in Complex Systems [10.7]. In view of the enormous range of properties and materials covered by the topic it is not feasible or desirable to attempt to review the whole field in a chapter such as this. Instead the topic is approached from the viewpoint of a researcher who, having measured the dielectric *spectrum* (i.e. frequency-dependent complex permittivity) of a material sample, wishes to know what information can be taken from the measurements. Along the way the limits on the information content and the problems (and controversies) associated with the microscopic and molecular-scale interpretation will be identified. Emphasis will be placed on the physical concepts involved, but inevitably there will be some mathematical expressions whose features I aim to place in as simple a physical context as possible.

10.1 Definition of Dielectric Response

10.1.1 Relationship to Capacitance

Stated simply the dielectric response of a material is its response to an electric field within it. Let us start in the simplest way with some basic macroscopic definitions. Imagine that we have a flat slab of our material of thickness d with electrodes of area A on each opposing surface, and we apply a potential difference between opposing sides (Fig. 10.1). Since the material is a dielectric our system is a capacitor and electric charges $\pm Q$ will be stored on the surfaces between which the potential difference V is applied with Q given by

$$Q = CV, \quad (10.1)$$

where C is the capacitance of the system. For the sample geometry considered C is given by the expression

$$C = (\epsilon_0 \epsilon_r A) / d. \quad (10.2)$$

Here the factor ϵ_0 is a fundamental constant termed the permittivity of free space ($\epsilon_0 = 8.854 \times 10^{-12} \text{ F m}^{-1}$) and ϵ_r is the permittivity of the material relative to that of free space and hence is termed the relative permittivity. Of course it is a pure number, which is a material property that contains information about the way the material responds to the application of the potential difference. Since however, the replacement of our sample by a vacuum yields a capacitance given by

$$C = (\epsilon_0 A) / d, \quad (10.3)$$

i.e. $\epsilon_r = 1$, the information about the response of the material to the electric field is contained in a factor χ ,

Fig. 10.1 A schematic representation of a dielectric in the form of a parallel-sided slab of surface area A and thickness d that has acquired surface charges $+Q$ and $-Q$ as a result of a potential difference applied across it. After [10.8]

which is called the susceptibility of the material and is given by

$$\chi = \epsilon_0(\epsilon_r - 1). \quad (10.4)$$

Noting that the electric field for the parallel electrode geometry described is given by $E = V/d$ and that the electrostatic flux density (electric displacement field) D within the material is $D = Q/A$, allows (10.1) and (10.2) to be transformed into the familiar constitutive relationship,

$$D = \epsilon_0 \epsilon_r E = \epsilon_0 E + \chi E \quad (10.5)$$

which is valid irrespective of the geometry. Here the response of the material has been explicitly separated out in the form of an additive term that is called the electric polarisation P , which has dimensions of charge/area or more familiarly electric dipole moment density (electric dipole moment/volume), and is given by

$$P = \chi E. \quad (10.6)$$

An electric dipole occurs when electric charges of opposite polarity are separated in space and the magnitude of the dipole moment is given by $\mu = \delta r$, where δ is the magnitude of the charge and r is the separation vector. The connection between P as defined above and the dipole moment density can be easily seen once it is recognised that the separation of the charges $\pm Q$ by the inter-electrode separation d constitutes a macroscopic dipole moment of magnitude Qd contained within the volume Ad . The definition of the polarisation as the dipole moment density makes it clear that the dielectric response to an electric field relates to the generation of a net dipole per unit volume in the material. In most cases the dielectric has a zero net dipole moment in the absence of an applied electric field and the action of the electric field is to produce one. Some materials such as electrets [10.9] and ferroelectrics lack a centre of symmetry, however, and possess a nonzero polarisation in the absence of an electric field. Therefore the definition of the polarisation P in (10.6) that is applicable to all cases is that P is the *change in net dipole moment density* produced by the applied field.

10.1.2 Frequency-Dependent Susceptibility

The outline given above has been written as if the electric field within the material was a static field ($f = 0$)

but (10.6) is equally valid if the field oscillates with a circular frequency ω ($\omega = 2\pi f$, where f is the frequency in Hertz). In this case (10.6) becomes

$$\mathbf{P}(\omega) = \chi(\omega)\mathbf{E}(\omega), \quad (10.7)$$

where $\mathbf{E}(\omega) = \mathbf{E}_0 \exp(i\omega t)$.

The fundamental reason for the dependence of $\mathbf{P}(\omega)$ upon the frequency of the alternating-current (AC) field, as in (10.7), can be envisaged by constructing a general picture of the way that a material responds to an electric field. Let us imagine that we have our material in thermal equilibrium in the absence of an electric field and we switch on a constant field at a specified time. The presence of the electric field causes the generation of a net dipole moment density (or change in one already existing). This alteration in the internal arrangement of positive and negative charges will not be instantaneous. Instead it will develop according to some equation of motion appropriate to the type of charges and dipole moments that are present. Consequently some time will be required before the system can come into equilibrium with the applied field. Formally this time will be infinity (equivalent to an AC frequency of zero), but to all intents and purposes we can regard the system as coming into equilibrium fairly rapidly after some relevant time scale, τ , with the polarisation approaching the static value $\mathbf{P} = \mathbf{P}(0)$ for $t \gg \tau$. If now we think of the electric field as reversing sign before equilibrium is reached, as is the case for an AC field at a time $t = 1/4f$ after it is switched on, it is clear that the polarisation will not have reached its equilibrium value before the field is reversed and hence that $\mathbf{P}(\omega) \lesssim \mathbf{P}(0)$, and $\chi(\omega) \lesssim \chi(0)$. The frequency dependence of the dielectric susceptibility $\chi(\omega)$ is therefore determined by the equation of motion governing the evolution of the ensemble of electric dipole moments.

In general $\chi(\omega)$ will be a complex function with a real component $\chi'(\omega)$ defining the component of $\mathbf{P}(\omega)$ that is in phase with the applied AC field $\mathbf{E}(\omega) = \text{Re}[\mathbf{E}_0 \exp(i\omega t)] = \mathbf{E}_0 \cos(\omega t)$, and $\chi''(\omega)$ defining the component that is 90° out of phase. The conventional form is given by

$$\chi(\omega) = \chi'(\omega) - i\chi''(\omega), \quad [i = \sqrt{-1}]. \quad (10.8)$$

It is easy to see that $\chi'(\omega)$ determines the net separation of charge with the dielectric in the form of a macroscopic capacitor, but the nature of $\chi''(\omega)$ is not so obvious. The answer lies in considering the *rate of change of polarisation*, $d[\mathbf{P}(\omega)]/dt$. This has the dimensions of a current density (current/area), is sometimes termed

the polarisation current density, and is given by,

$$\begin{aligned} d[\mathbf{P}(\omega)]/dt &= [\chi'(\omega) - i\chi''(\omega)] d[\mathbf{E}(\omega)]/dt \\ &= [\chi'(\omega) - i\chi''(\omega)] i\omega[\cos(\omega t) \\ &\quad + i\sin(\omega t)]\mathbf{E}_0. \end{aligned} \quad (10.9)$$

Thus $\chi''(\omega)$ determines the real component of the polarisation current density that is in phase with the electric field, i.e. $\mathbf{J}_{\text{pol}}(\omega)$ given by

$$\mathbf{J}_{\text{pol}}(\omega) = \chi''(\omega)\omega\mathbf{E}_0 \cos(\omega t) = \sigma_{\text{AC}}(\omega)\mathbf{E}_0 \cos(\omega t). \quad (10.10)$$

Here $\chi''(\omega)\omega = \sigma_{\text{AC}}(\omega)$ is the contribution to the AC conductivity due to the polarisation response to the electric field. If we remember Joule's Law for the power dissipated thermally by an electric current, i.e. power lost = IV , then we can see that $\chi''(\omega)\omega(\mathbf{E}_0)^2$ is the power dissipated per unit volume resulting from the generation of a net polarisation by the electric field, i.e. the power dissipation density. The imaginary susceptibility $\chi''(\omega)$ is often termed the power dissipation component. It arises because the electric field has to carry out work on the dielectric in order to produce a net dipole moment density. Some of this energy is stored in the charge separations and is recoverable in an equivalent way to the elastic energy stored in a spring. The rest of the energy is used to overcome the friction opposing the establishment of the net dipole density. This energy is transferred to the dielectric in an unrecoverable way, i.e. it is dissipated within the dielectric. It can be seen that $\chi''(\omega)$ is dependent upon the form of the equations of motion governing the evolution of the net dipole moment density under the action of an electric field.

10.1.3 Relationship to Refractive Index

Equation (10.7) can be regarded as relating to the polarisation response purely to an oscillating electric field, but of course all electromagnetic waves contain such a field. In general the topic of dielectric response includes the response of the material to the electric field component of an electromagnetic field, i.e. the electromagnetic spectrum of a material is a form of dielectric response. This form of response is generally characterised by a complex frequency-dependent refractive index $n^*(f)$, with

$$n^*(f) = n(f) - i\kappa(f), \quad (10.11)$$

where n is the real refractive index expressing the velocity of light in the material, v , as $v = c/n$, and κ is the

absorption coefficient, which defines the reduction of intensity of light of frequency f as it passes through the medium due to absorption of the photons by the medium, i. e. it relates to energy dissipated from the electromagnetic wave. The absorption coefficient can be determined from the Beer–Lambert law,

$$I = I_0 \exp(-4\pi\kappa fz/c). \quad (10.12)$$

For nonmagnetic materials an equivalence can be established between n^* and the relative permittivity (see [10.10] for example). If we think of two slabs of dielectric material placed in contact with an electromagnetic wave passing through them, the component of the field \mathbf{D} perpendicular to the boundary is unchanged as the wave passes from one medium to another. Essentially the same electrostatic flux passes through the same perpendicular area. Equation (10.5) gives the ratio of the electric fields in the two dielectric media to the inverse of the ratio of their relative permittivities. A comparison with Snell's law [10.10, 11] then

yields

$$\varepsilon_r = [n^*(f)]^2. \quad (10.13)$$

Measurement of the dielectric response of a material involves the determination of the polarisation and its frequency dependence in some form or other. This can be carried out in a large number of ways such as the absorption spectra of electromagnetic radiation as has been described above as well as the application of an AC electric field across a sample of defined dimensions. Those readers interested in the technical details of the measurement systems are referred to the general literature, which has an enormous number of works on these experimental techniques (see for example [10.12] for bridge techniques and [10.13] for recent microwave techniques). This chapter will have a different focus. It will in essence be a discussion of the microscopic origins of the polarisation $\mathbf{P}(\omega)$ and the physical reasons for its variation in frequency so that data obtained from such measurements can be used to gain information relevant to the nature of the material to be studied.

10.2 Frequency-Dependent Linear Responses

In this context a linear response is one in which $\mathbf{P}(\omega)$ is only dependent upon the first power of the electric field, i. e. $\chi(\omega)$ is independent of the electric field. The general form of frequency dependence expected for $\varepsilon(\omega) = [\varepsilon_0 + \chi(\omega)]$ is shown schematically in (Fig. 10.2), where it can be seen that two basic types of response can be distinguished: a resonance response at high frequencies in the quantum region, and what is termed a relaxation response at lower frequencies.

10.2.1 Resonance Response

Although our main topic in this chapter will be the relaxation behaviour I will start with the resonance response as this has been dealt with extensively [10.14] from the spectroscopic viewpoint. Here we shall approach it from the perspective of its identity as a dielectric response with the intention of identifying basic features that also occur in relaxation responses. The equation of motion is familiar: this form of response relates to a *net* electric dipole moment, ϕ , that undergoes damped simple harmonic oscillation at a natural oscillation frequency $\Omega = 2\pi\nu$ in the absence of an electric field,

$$d^2\phi/dt^2 + \gamma d\phi/dt + \Omega^2\phi = 0. \quad (10.14)$$

Fig. 10.2 Schematic representation of the frequency dependence of relaxation and resonance responses

The interpretation of (10.14) is not as obvious as it seems. We have to remember that we are always dealing with a sample of material that contains an enormous number of molecules or molecular moieties. Two types of situation may lead to this form of equation of motion. In one case a fluctuation in the positions of *groups* of positive and negative charges may form an oscillating net dipole moment. Plasma oscillations, found in metals [10.15], are an example of this type of behaviour. In the other case, individual molecules may possess identical dipoles oscillating independently at a frequency Ω .

Equation (10.14) then describes the behaviour of a *net* dipole moment produced by a fluctuation in the system of molecules independent of an applied electric field. Such fluctuations are deviations from the average equilibrium state produced by random impulses that act only for an infinitesimal time at $t = 0$, and (10.14) describes the subsequent evolution of the fluctuation. In both cases the damping (friction) term $\gamma d\phi/dt$, where γ is the damping factor, expresses the way in which the fluctuation dies away in the absence of an applied electric field and the net dipole moment density of the system returns to zero.

The situation applying in the case of most spectroscopic responses relates to dipole density fluctuations in which individual molecules contribute oscillating dipoles, and it is this form of behaviour that will be used to illustrate the resonance form of response. The first thing we have to do is to ask what kinds of dipole moments oscillate in our material at frequencies in the range $\nu \gtrsim 5 \times 10^{10}$ Hz where most resonance responses are found. The answer to this question lies in the electronic structure of the atoms, ions and molecules that make up our material. The uncertainty principle states the energy of a system cannot be specified at any precise instant of time. This means that the electronic structure of atoms and molecules is allowed to continuously fluctuate between quantum states as long as the average energy over a period of time remains constant. The

averaging time is determined by the uncertainty relationship between energy and time. The molecule is thus continuously moving back and forth between ground state and its excited states. These quantum fluctuations (between ground and excited states) displace the negative charge of the electron cloud with respect to the positive charge of the nucleus, and produce oscillating dipoles, termed transition dipoles (Fig. 10.3a). Their oscillation frequencies have specific values depending upon the energy difference between excited and ground quantum states of the species concerned, typically in the range $\nu \gtrsim 4 \times 10^{14}$ Hz [10.14, 16]. These oscillating dipolar fluctuations give no net contribution to the dipole moment of the molecule or atom. The uncertainty principle similarly allows the nuclei of molecules, and the molecules themselves to vibrate and fluctuate between different vibration states. In many cases these nuclear fluctuations produce dipole moments [10.10, 16, 17] (Fig. 10.3b), which typically oscillate in the frequency range 4×10^{14} Hz $\gtrsim \nu \gtrsim 5 \times 10^{10}$ Hz. As with the electronic transition dipoles, these vibration fluctuations do not contribute to the dipole moment of the molecule or system of molecules.

When an AC electric field, such as that provided by an electromagnetic wave, is applied to the material, it couples to the transition dipoles to give a force that drives the system. As a result the population of dipoles is altered such that there is now a *net* average density of transition dipole moments. This oscillates with the frequency of the *field*, i.e. the system is polarised as defined by (10.7). Since transition dipoles do not contribute to a permanent dipole moment of a molecule, the net dipole moment density produced by the electric field is referred to as an induced dipole moment density. The response of the system to an electric field oscillating at a frequency ω is essentially obtained by adding the driving force to (10.14) and determining the solution for ϕ that oscillates with the same frequency, i.e. $\phi(t) \propto e^{i\omega t}$. The components of the frequency-dependent relative susceptibility, $\chi_r(\omega) = \chi(\omega)/\epsilon_0$, then take the form

$$\chi'_r(\omega) = \frac{\chi_0 \Omega^2 (\Omega^2 - \omega^2)}{(\Omega^2 - \omega^2)^2 + \omega^2 \gamma^2}, \quad (10.15)$$

$$\chi''_r(\omega) = \frac{\chi_0 \Omega^2 \omega \gamma}{(\Omega^2 - \omega^2)^2 + \omega^2 \gamma^2}. \quad (10.16)$$

These equations exhibit the typical signature of a resonance response such as shown in Fig. 10.2. The imaginary component $\chi''_r(\omega)$ goes through a peak at $\omega = \Omega$ (the resonance frequency). The real component $\chi'_r(\omega)$ exhibits a rise in positive value as the driving

Fig. 10.3a–d Schematic representation of the various forms of dipole fluctuations: (a) atomic dipole, (b) dipoles formed by bending and stretching motion of a tri-atomic molecule of the form A–B–A, (c) net dipole fluctuation produced in a system of permanent dipoles, (d) reorienting dipole formed by transfer of an ion between two different centres of vibration. In all cases the *light arrow* shows the net dipole

frequency ω approaches the natural frequency Ω from below, passes through zero when ω and Ω are equal, and rises towards zero from a negative value when $\omega \gg \Omega$. In some cases the exact frequency dependence of the relative susceptibility can be slightly different from that given above. Typically the peak in $\chi_r''(\omega)$ is broadened due to the possibility that either the resonance frequencies of different transitions of the same molecule can be close together and their responses can overlap, or that local electrical interactions between molecules cause the transition energies of individual molecules to be slightly shifted in energy.

As long as the transition energies are sufficiently far apart to be resolved experimental data of the resonance type will yield three pieces of information, which can be related to the electronic (or vibration) structure of the molecules. These are: (a) the natural oscillation frequency Ω , (b) the damping constant γ , and (c) the amplitude factor χ_0 . The natural frequency ν is equal to the energy difference of the electronic states between which the fluctuation occurs, ξ , divided by Planck's constant i. e. $\nu = \xi/h$, and so provides information about the different quantum states in relation to one another. The amplitude factor χ_0 is proportional to the square of the transition dipole and therefore yields information on the relative rearrangement of positive and negative charges within the molecule by the transition fluctuation. Damping in these types of systems arises from the sharing of the transition energy between many energy states of the molecule and its vibrations. It removes energy from the specific oscillating dipoles for which the field produces a net dipole moment density. It may act through a delay in returning energy to the electromagnetic wave, i. e. incoherent reradiation, or by transferring it to other energy states where it cannot be reradiated. The damping therefore expresses the way that the energy transferred from the electromagnetic field to the molecule is absorbed and dissipated in the system. The damping factor γ often will have a complicated form. There is of course one other piece of information that is implied by data that fit (10.15, 16) and that is that the equation of motion for the natural oscillating dipole moments is given by (10.14). In some cases, however, the damping factor may be frequency dependent as a result of changes in the interaction between different energy states of the system that occur on the same time scale as the relaxation time, $1/\gamma$. The equation of motion will now have a different and more complicated form than that of (10.14).

The above outline of spectroscopic responses is of necessity very sketchy as it is not the main theme of this chapter, and is dealt with in detail in many stan-

dard textbooks (e.g. *Heitler* [10.14]). There are however, a number of general features that can be used as a guide to what happens in the *linear* relaxation response. In the first place the dipoles involved are a property of natural fluctuations of the system, in this case quantum fluctuations in molecules. They are not produced by the electric field. In the absence of an electric field the fluctuating dipoles do not contribute to the net dipole moment of the system, in this case individual molecules. The action of the electric field in linear responses is solely to alter the population of the fluctuations such that a net dipole moment density is produced. This is achieved in the resonance cases considered above by the production of a net density of molecules in an excited state proportional to $\chi_0 E_0$. The irreversible transfer of energy from the electric field to the system relates to the sharing of this energy between the oscillating dipoles coupled to the electric field, and many equi-energetic states of the system that do not couple directly to the electric field. The energy shared in this way is dissipated among the many connected states. Dissipation is an essential consequence of natural fluctuations in an ensemble [10.18] and expresses the requirement that the fluctuation die away to zero at long times. The function $\phi(t)$ must therefore approach zero as t tends to infinity. In the absence of an electric field dipole density fluctuations utilise energy gained transiently from the ensemble and return that energy via the dissipation mechanism. When however an electric field is present, the relative number of fluctuations with dipole moments in different directions is altered and the dissipation term irreversibly transfers energy from the electric field to the ensemble.

10.2.2 Relaxation Response

We turn now to the relaxation response. The simplest way to view this behaviour is as an overdamped oscillation of the net dipole moment density, i. e. one for which $\gamma^2 > 4\Omega^2$. There are a number of ways of addressing this situation and below I shall develop the description starting from the simplest model whose behaviour is rarely found in condensed matter.

The Debye Response

In this case we can neglect the force constant term in (10.14), i. e. the term $\Omega^2\phi$. This leads to an equation of motion with the form

$$d\phi/dt + \gamma\phi = 0. \quad (10.17)$$

The solution to this equation is the very familiar exponential form, $\phi(t) \propto e^{-t/\tau}$. Equation (10.17) can be

interpreted by taking on board the lessons from the resonance response. As before we have to view it as describing the behaviour of a natural fluctuation in our system that produces a net dipole moment density as the result of a random impulse at $t = 0$. Now however, there is no evidence for dipole oscillation, so we are not looking at the quantum fluctuations of electronic charge clouds and nuclei positions of molecules. In this case the response originates with the permanent dipoles that many molecules possess due to the asymmetry of their atomic construction. We should also remember that, though atoms do not possess a permanent dipole moment, ion pairs in a material will act as dipoles. Such systems contain a large number (ensemble) of permanent dipoles and this ensemble will obey the laws of thermodynamics. Therefore, with the exception of such materials as electrets and ferroelectrics the orientation of the permanent dipoles will be random in the absence of an electric field, i.e. the *average* net dipole moment of the system will be zero. Thermodynamic ensembles are however described by distributions that allow for fluctuations about the defined average values, thus for example canonical ensembles allow for fluctuations in energy about a defined average energy content, and grand canonical ensembles allow for fluctuations in the number of effective units (e.g. net dipole moments) as well. In the case of dipole responses we are looking at fluctuations that involve the orientations of the permanent dipoles and hence create a net dipole density (Fig. 10.3c,d). Such fluctuations are natural to the ensemble, but are transient, i.e. as in Sect. 10.2.1 $\phi(t) \rightarrow 0$ as $t \rightarrow \infty$. Equation (10.17) describes the way in which such a local fluctuation in the dipole moment density decays (regresses) to zero, i.e. the ensemble relaxes. An applied electric field couples with the permanent dipoles to produce a torque that attempts to line the dipole with the electric field vector where its energy is lowest. Consequently the linear response of the system to the application of an electric field is an increase in the population of the permanent dipole fluctuations with a component oriented in the field direction as compared to those which have components oriented in the reverse direction. This relative change in the populations of the natural fluctuations of the system gives a net dipole moment density that is driven at the frequency of the electric field as in (10.7) [10.19].

As in the resonance case the polarisation can be obtained by adding the AC driving force oscillating at frequency ω to (10.17) and determining the solution for ϕ oscillating with the same frequency. The corresponding relative susceptibility components have the

form

$$\chi_r'(\omega) = \frac{\chi_0}{1 + \omega^2/\gamma^2}, \quad (10.18)$$

$$\chi_r''(\omega) = \frac{\chi_0\omega/\gamma}{1 + \omega^2/\gamma^2}. \quad (10.19)$$

These functions show a peak in the imaginary susceptibility component, $\chi_r''(\omega)$, at a frequency $\Omega = \gamma$, which is sometimes called the loss peak frequency since $\chi_r''(\omega)$ is associated with the dissipation of energy, or equivalently the loss of energy from the driving electric field. The real component of the susceptibility, $\chi_r'(\omega)$, changes monotonically from zero at high frequencies to a limiting low-frequency value of χ_0 . This is termed the dielectric dispersion.

Equations (10.17–10.19) define what has come to be known as the Debye response after *P. Debye* who first addressed the nature of relaxation dielectric responses [10.1]. It is characterised by two pieces of information: the magnitude of the dispersion χ_0 and the damping factor γ , more usually defined via the relaxation time $\tau = 1/\gamma$ of the dipole density fluctuations. The dispersion magnitude χ_0 is a measure of the net change in dipole density fluctuations that can be produced by a unit field (i.e. $E_0 = 1 \text{ V m}^{-1}$), and is proportional to the square of the individual permanent dipole moments. As with the resonance response an exact fit between the relaxation response data and (10.18), (10.19) implies a specific form for the equation of motion of the dipole density fluctuations of the permanent dipole ensemble, i.e. that of (10.17).

Frequency-Dependent Dielectric Response in Condensed Matter

In practice the Debye response is rarely observed outside of the gas phase. Instead the experimental data can usually be characterised through fractional power laws in the frequency dependence of $\chi_r''(\omega)$ [10.6, 8, 20] in the regions away from the peak (see Fig. 10.4), i.e. for $\omega \gg \gamma$, and $\omega \ll \gamma$, giving

$$\chi_r'(\omega) \propto \chi_r''(\omega) \propto \omega^{n-1}, \quad \omega \gg \gamma, \quad (10.20)$$

$$\chi_r'(0) - \chi_r'(\omega) \propto \chi_r''(\omega) \propto \omega^m, \quad \omega \ll \gamma. \quad (10.21)$$

Here n , and m are fractional exponents, i.e. $0 < n, m < 1$. This general form was first defined empirically as the Havriliak–Negami function [10.21, 22]. A number of special cases have been identified [10.5, 8]. Thus for example the Cole–Cole function is given by $n + m = 1$. When $m = 1$, and $0 < n < 1$, the Cole–Davidson form is produced, which obeys (10.20) and

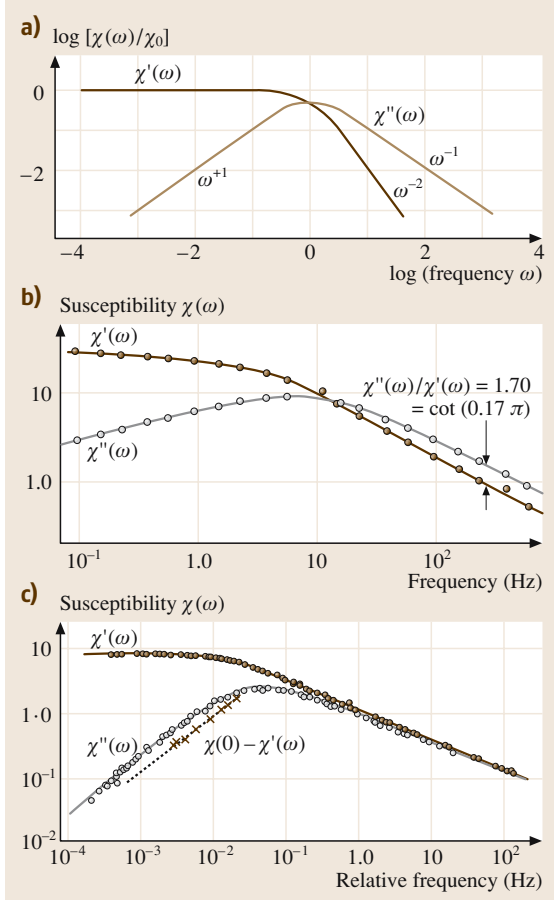

Fig.10.4 (a) Schematic drawing of the Debye response. (b), (c) Examples of measured data fitted to the response function $\chi(\omega)/\chi(0) \propto [(1 + i\omega\tau)^{n-1} {}_2F_1(1-n; 1-m; 2-n; (1+i\omega\tau)^{-1})]$ resulting from the response function $\phi(t)$ of (10.22). The function ${}_2F_1(,; ;)$ is the Gaussian hypergeometric function [10.25]. Plot (b) data from irradiated tri-glycine sulphate (TGS); Plot (c) data from polyvinylacetate. After [10.26]

follows $\chi_r''(\omega) \propto \omega^m$ ($m = 1$) for $\omega \ll \gamma$ but without $\chi_r''(\omega)$ being proportional to $\chi_r'(0) - \chi_r'(\omega)$ as in (10.21).

The physical theory of Dissado and Hill [10.23, 24] yields analytical expressions for $\chi_r'(\omega)$ and $\chi_r''(\omega)$ that contain both the Debye and Cole–Davidson functions as exact limiting cases, and the Cole–Cole and Havriliak–Negami functions as approximations with only minor differences in the curvature in the region of the peak in $\chi_r''(\omega)$. The frequency-dependent susceptibility given by this theory has come to be known as the Dissado–Hill function and is defined in terms of a hypergeometric

function [10.25], which is an infinite series with similarities to that of the exponential function. The reader is referred to [10.23, 24] for details. Unlike the empirical functions the Dissado–Hill dielectric response function has a clearly defined equation of motion for $\phi(t)$ [10.24],

$$\frac{d^2\phi}{dt^2} + \frac{[2+n+(t/\tau)]}{t} \frac{d\phi}{dt} + \frac{[n+(t/\tau)(1+m)]}{t^2} \phi = 0. \quad (10.22)$$

This equation has an analytical solution for $\phi(t)$ in terms of a confluent hypergeometric function [10.25], which has the limiting behaviour $\phi(t) \propto t^{-n}$ at times $t < \tau = 1/\gamma$ and $\phi(t) \propto t^{-(1+m)}$ when $t > \tau = 1/\gamma$. When $m = 1$ the solution is $\phi(t) \propto t^{-n} \exp(-t/\tau)$ giving the Cole–Davidson susceptibility function, and the Debye response function $\phi(t) \propto \exp(-t/\tau)$ is obtained when $n = 0$ and $m = 1$. The general analytical function for $\phi(t)$ was first derived in [10.27] and later re-derived and its equation of motion discussed in [10.23, 24] to which the reader is referred for details. The form of (10.22) illustrates clearly the development of the relaxation response from short-time high-frequency damped harmonic oscillations, characterised by (10.14), as a consequence of time-dependent damping functions and oscillation frequencies. More specifically the damping function approaches a constant value $1/\tau$ (equivalent to γ) at long times, while the oscillation frequency approaches zero. In contrast the Debye model assumes that the dipole motions are overdamped motions with no time-dependent transition from the damped oscillations occurring at short times. Of course there are many ways that time-dependent damping functions and oscillation frequencies may be introduced, most of which involve making similar approximations to that of Debye as regards the ensemble forces that control these factors, but only the specific forms of (10.22) give the power-law frequency dependencies observed in the susceptibility (10.20), (10.21). These forms are produced because the dipole density fluctuations retain some memory of the restoring and damping forces that act on it over very long periods of time, i.e. these forces are not random impulses. The reader is referred to [10.24] for more detail.

The Response Function

A different approach may be taken to deriving the frequency-dependent susceptibility of linear responses. Returning to (10.14), (10.17), and (10.20) it can be seen that the solutions for $\phi(t)$ in the absence of a driving field give the time evolution of the dipole density

fluctuation caused by a dipole generating impulse at $t = 0$, i.e. the natural motions of the system. The resulting expression for $\phi(t)$ is called the response function [10.19], and the complex susceptibility is obtained through (10.23).

$$\begin{aligned}\chi_r(\omega) &= \chi'_r(\omega) - i \chi''_r(\omega) \\ &= \text{Lt}_{\varepsilon \rightarrow 0} \left[\int_0^{\infty} \phi(t) e^{-i\omega t - \varepsilon t} dt \right].\end{aligned}\quad (10.23)$$

Here ε is an infinitesimal quantity that is taken to zero after the integral has been carried out. This equation is valid for all linear dielectric responses. The requirement that $\phi(t) \rightarrow 0$ as $t \rightarrow \infty$ for natural fluctuations ensures that $\chi'_r(\omega)$ and $\chi''_r(\omega)$ remain finite. The equations of motion, (10.14), (10.17), and (10.22) have solutions for $\phi(t)$ that can be transformed in this way to yield analytical expressions for the frequency-dependent susceptibility. An important consequence of (10.23) is that the frequency dependencies of $\chi'_r(\omega)$ and $\chi''_r(\omega)$ contain the same information since they are Laplace transforms of the same time-dependent function. This also means that a frequency-dependent conductivity $\sigma(\omega) \equiv [\omega \chi''_r(\omega)]$ contains no more information than the equivalent dielectric dispersion $\chi'_r(\omega)$. In fact the linear susceptibility components $\chi'_r(\omega)$ and $\chi''_r(\omega)$ are related to one another through the Kramers–Kronig relationships [10.5, 6]

$$\chi'_r(\omega) = \frac{2}{\pi} \int_0^{\infty} \frac{x \chi''_r(x)}{x^2 - \omega^2} dx, \quad (10.24)$$

Fig. 10.5 The fit between the response function $\phi(t)/\phi(0) \propto (t/\tau)^{-n} e^{-t/\tau} {}_1F_1(1-m; 2-n; t/\tau)$ from (10.22) (where ${}_1F_1(;);$ is the confluent hypergeometric function [10.25]), and experimental data for amorphous gallium arsenide. After [10.24]

$$\chi''_r(\omega) = -\frac{2\omega}{\pi} \int_0^{\infty} \frac{\chi'_r(x)}{x^2 - \omega^2} dx. \quad (10.25)$$

The imaginary contribution from the pole at $x = \omega$ is excluded from these integrals. Although formally values of $\chi'_r(\omega)$ and $\chi''_r(\omega)$ are required over the frequency range from zero to infinity, the reciprocal relationships are adequately reproduced as long as the major part of the dispersion from any specific relaxation process is used.

Equation (10.23) means that linear dielectric responses are characterised through the time dependence of $\phi(t)$. This led *Williams and Watts* [10.28] to approach the description of the frequency dependence commonly observed by proposing that the exponential behaviour of

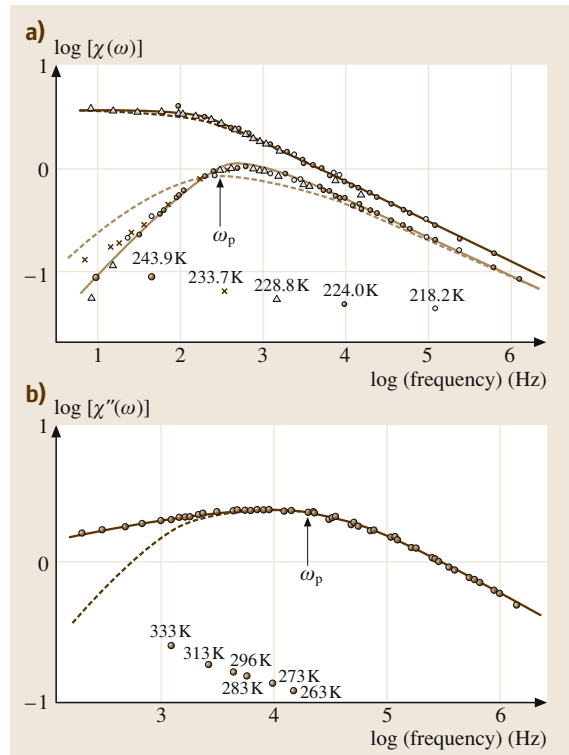

Fig. 10.6a,b Two examples of the fit between the susceptibility functions resulting from the response function $\phi(t)$ of (10.22) (continuous line) and (10.26) (broken line) and experimental master curves: (a) Nematic form of N-(2-hydroxy-4-methoxybenzylidene)-pn-butylaniline (OHMBBA), and (b) Polyallylbenzene. The shift of the representative point required to construct the master curve is marked on the plot. After [10.24]

$\phi(t)$ resulting from the Debye model, (10.17), should be generalised to the form

$$\phi(t) \propto (t/\tau)^{-n} \exp \left[-(t/\tau)^{1-n} \right]. \quad (10.26)$$

This expression is sometimes called the expanded exponential function or the Kohlrausch–Williams–Watt function, as it was later found that it was first proposed in [10.29] for mechanical responses. It is not known to possess a simple equation of motion such as (10.14), (10.17), and (10.22) but its relaxation function $\Phi(t)$, defined by $\Phi(t) = \int_t^\infty \phi(t) dt$ [10.19] obeys a relaxation equation of the form of (10.17) with a time-dependent damping factor $\gamma(t) \propto t^{-n}$. The corresponding frequency-dependent susceptibility has the same power-law form as (10.20) for $\omega \gg \gamma = 1/\tau$, but

exhibits a slowly varying decrease of slope as the frequency γ is approached from below that, with suitable choices for the value n , can approximate a power law for $\chi_r''(\omega)$ such as is defined in (10.21). The relationship between experimental data for $\phi(t)$ and that derived in the Dissado–Hill cluster model, i. e. the solution to (10.22), is shown in Fig. 10.5. It can be seen that the data and the function for $\phi(t)$ approaches zero as t tends to infinity, with the time power law $t^{-(1+m)}$, but accurate experimental data for times several decades beyond τ is required if this behaviour is to be distinguished from that of (10.26). A better means of distinguishing the two results can often be had by recourse to their appropriate frequency-dependent susceptibilities, see Fig. 10.6.

10.3 Information Contained in the Relaxation Response

As described in Sect. 10.2.2 relaxation responses contain three pieces of information. The strength of the coupling of dipole density fluctuations to the electric field characterised by χ_0 , a characteristic relaxation frequency $\gamma = 1/\tau$, where τ is the characteristic relaxation time, and the relaxation dynamics characterised by the frequency dependence of $\chi_r'(\omega)$ and $\chi_r''(\omega)$. This latter feature is open to different interpretations, as will be discussed later.

10.3.1 The Dielectric Increment for a Linear Response χ_0

The dielectric increment is proportional to the square of the permanent dipole moments that give rise to the dipole density fluctuation. It is a feature of the dielectric response that does not usually receive the most attention, mainly because a quantitative relationship to the molecular physics of the relaxation process is often difficult to achieve. Nevertheless it has been used to determine the dipole moments of polar molecules using measurement in the gas phase or if necessary dilute solutions in a non-polar solvent. In these cases the permanent molecular dipoles, μ , can be assumed to be independent of one another and to be able to adopt all orientations with equal probability in the absence of an electric field, i. e. all dipole moment orientations are at the same energy. This section starts by outlining the derivation of χ_0 for this situation even though this is not the topic area of this book and chapter. The aim is to demonstrate the procedure and bring out the assumptions involved so that the

more complicated nature of dipole density fluctuations in condensed-state materials can be better appreciated.

Independent Free Dipoles

In an electric field a dipole that is at an angle θ to the field direction is at the energy $-\mu E \cos \theta$. Those molecules aligned with the electric field are therefore at the lowest energy. The thermal motions of the molecules will however tend to randomise the dipole orientations and the probability of finding a dipole with an orientation angle θ becomes $\exp(\mu E \cos \theta / k_B T)$. The average value of $\mu \cos \theta$ is given by

$$\begin{aligned} M &= \langle \mu \cos \theta \rangle \\ &= \frac{\int_0^\pi \mu \cos \theta \exp(\mu E \cos \theta / k_B T) \sin \theta d\theta}{\int_0^\pi \exp(\mu E \cos \theta / k_B T) \sin \theta d\theta} \end{aligned} \quad (10.27)$$

and the contribution to the static polarisation is given by $N \langle \mu \cos \theta \rangle$, where N is the number of permanent dipoles per unit volume. The term independent of the electric field is zero because all orientations are equally probable in the absence of the field. Equation (10.27) results in a nonlinear function in the electric field E for M , which is called the Langevin function, $L(\mu E / k_B T)$, with,

$$L(\mu E / k_B T) = \coth(\mu E / k_B T) - (k_B T / \mu E). \quad (10.28)$$

This function saturates at unity for very high values of $\mu E/k_B T$, reflecting the total alignment of all the permanent dipoles in the electric field. At low fields defined by $\mu E/k_B T \ll 1$, $L(\mu E/k_B T)$ is a linear function of E and gives the linear dielectric increment as

$$\chi_0 = \mu^2/3k_B T. \quad (10.29)$$

Dipoles in Condensed Matter

In condensed-phase systems, particularly solids, the approximations that lead to the Langevin function and (10.29) no longer apply, and hence these expressions no longer hold. In the first place the dipoles are constrained by the local structure and in general will not be able to assume all orientations with equal probability in the absence of an electric field. In the second place we cannot assume that the dipoles are independent of one another. This dependence may arise in more than one way. For example there may be electrostatic interactions between the dipoles, such as would be responsible for the formation of ferroelectric and anti-ferroelectric states. However when the dipoles concerned are of a low concentration such as those that originate with impurities, lattice defects, interstitial ions etc., these dipole–dipole interactions may be weak. The dipoles concerned may also be arranged in such a way that even though they can adopt one or more alternative orientations their dipole–dipole interactions essentially cancel, such as might be expected in dipole glasses [10.30]. The common way to deal with this situation is to assume that a dipole representative of the average dipole in the ensemble experiences the average electric field of all the other dipoles. This is called the *mean-field* approach [10.31]. Since the mean field will be a function of the average dipole moment due to the applied electric field it is usually possible to construct an equation that can be solved to yield M and hence χ_0 . Another way in which the dipoles can interact arises because permanent dipoles are part of the lattice structure of the material. Those permanent dipoles that lead to a polarisation in the presence of an electric field must have two or more local orientations available to them, i. e. they must be able to adopt a different orientation that in the presence of an electric field has a lower energy. Any such change will inevitably alter the local atomic and molecular interactions around the dipole that has moved. This effect will travel through the structure and influence other permanent dipoles through changes in atomic and molecular positions in its environment [10.32]. The strength of such interactions will vary depending of the type of dipole and the way that it is connected to the structure. For example reorientable

dipoles formed by small interstitial (or substitution) ions may not interact very strongly with the surrounding lattice, whereas polar groups attached to a polymer chain will in many cases interact very strongly when they adopt a different orientation. Similarly the reorientation of polar molecules in liquids may be expected to distort their surrounding solvent cage and create a disturbance that will be transmitted to other polar molecules. The special feature of this form of interaction is that it is transmitted along specific directions depending upon the lattice structure and hence is nonisotropic.

Order–Disorder Ferroelectrics

These are materials in which the permanent dipoles possess two or a limited number of possible orientations. At high temperatures the dipoles are randomly distributed between the alternative orientations in the absence of an electric field. As the temperature is lowered the electrostatic field of the dipoles acts on any one dipole to make one of the orientations more preferable than the others. This causes the permanent dipole system to adopt a specific orientation at the Curie temperature T_c . The mean-field approach results in an expression for χ_0 that diverges at T_c , i. e.

$$\chi_0 \propto \mu^2/|(T - T_c)|. \quad (10.30)$$

This expression is so common to us that it is easy to overlook the physical meaning that it contains, which is much better expressed in the renormalisation group approach [10.33]. Essentially the interactions between the dipoles cause their orientation and dynamics to become correlated to some extent. As T_c is approached from above, the dipole fluctuations in the system are correlated over increasingly long distances and involve increasingly larger groups of individual dipole moments μ . The dielectric increment increases in proportion to a power of the correlation length $\xi \propto |(T - T_c)^{-\delta}|$ and a more exact form for χ_0 is

$$\chi_0 \propto \mu^2/|(T - T_c)|^\alpha. \quad (10.31)$$

At temperatures below T_c the material will possess domains in which all the dipoles are aligned together. Dipole fluctuations in this state have the opposite orientation to that of the polarity of the domain dipole that is they are *changes in net dipole moment density*, see Sect. 10.1.1. These dipole fluctuations also produce an electrostatic field that causes them to be correlated. As the temperature reduces their correlation length reduces and hence so does χ_0 . These materials show that the responding dipole in condensed-phase materials will not

always be that of individual molecular or ionic components of the system, they may in fact be groups of individual dipoles that respond as a single unit. In fact the susceptibility increment may be written in terms of an effective dipole moment that is also a power of the correlation length, i. e. $\mu_{\text{eff}} \propto (\xi)^{\alpha/2\delta}$.

Kirkwood Correlation Factor

The particular feature of the ferroelectric order–disorder transition is that the correlation between dipoles in the dipole fluctuations is temperature dependent. In general this will not be the case; instead we can expect the correlation to be dependent upon the lattice structure of the material, and hence independent of temperature except for discrete step changes when the material undergoes a phase transition. One way of allowing for these correlations is to introduce a factor g , termed the Kirkwood factor [10.10, 34], into the expression for χ_0 such that it becomes

$$\chi_0 \propto Ng\mu^2. \quad (10.32)$$

Here a value of $g = 1$ defines a system in which the dipoles are uncorrelated, i. e. they are independent of one another. Values of $g > 1$ indicate positive correlation i. e. the dipoles align in the same direction as in the ferroelectric case where g diverges as discussed. Values of $g < 1$ indicate dipoles that are anticorrelated i. e. pairs of dipoles tend to align in opposite directions. Both kinds of behaviour are known to occur.

General Features of the Temperature Dependence of the Dielectric Increment

Section 10.3.1 gives examples of behaviour in which an electric field imposes order, in terms of the polarity of the net dipole density fluctuations, upon an ensemble where the temperature acts as a disordering factor. In the case of independent free dipoles it is the applied field that attempts to align dipoles and for order–disorder ferroelectrics it is the electrostatic field of the other dipoles. It might therefore be expected that the temperature is always a factor that attempts to oppose the field and that the dielectric increment will decrease at high temperatures, but this is not always the case. For example, in situations where the dipole can adopt one of two orientations one of which is favoured by the local lattice structure, the equilibrium population will be heavily weighted towards the favoured orientation. The equilibrium value of M in such a region can be expressed as,

$$M = \mu \tanh[(\Delta_\chi/k_B T)], \quad (10.33)$$

where $2\Delta_\chi$ is the energy difference between the alternative orientations produced by the local structure. Here μ is the reorientable component of the dipole moment, see Fig. 10.7. An applied electric field that will favour the one orientation over the other will change the energy difference between alternative orientations from $2\Delta_\chi$ to $2(\Delta_\chi - \mu E)$. Differentiation with respect to E then gives the susceptibility increment as $\chi_0 \propto (\mu^2/k_B T) \cosh^{-2}(\Delta_\chi/k_B T)$, with the approximately activated form

$$\chi_0 \propto (\mu^2/k_B T) \exp(-2\Delta_\chi/k_B T) \quad (10.34)$$

holding when $\Delta_\chi/k_B T \gg 1$. Although (10.33) implies that regions exist where dipoles are aligned by the structure this does not necessarily mean that the material has a net dipole in the absence of an electric field. Such regions may be local and with dipole vectors randomly arranged by the structure. This behaviour has been found in ferroelectric ceramics [10.35, 36] in both the ferroelectric and paraelectric phases outside the transition region where T approaches T_c . Expression (10.34) indicates that in the appropriate temperature range the effect of the thermal fluctuations is effectively to increase the density of dipoles that can respond to the electric field, and that this overcomes any randomising behaviour. In contrast, at high temperatures ($\Delta_\chi/k_B T \ll 1$) the distribution of dipoles between the alternative orienta-

Fig. 10.7a,b Dipole reorientation between two potential wells: (a) shows the reorientable component of the dipole, (b) shows the potential-energy surface

tions becomes almost random and χ_0 approaches the free-dipole result (10.29).

In many experimental situations the value of the dielectric increment is essentially independent of temperature. It is difficult to see how this can occur in an ensemble where the dipole density fluctuations are produced by fluctuations in thermal energy about the average value, which couple to the electric field via changes in the heat content as in (10.27). However it may be possible to conceive of this behaviour as due to fluctuations in the configuration entropy of the molecular system, of which the dipole is a part, that take place without any change in the heat content. The effect of the field would be to change the configuration entropy S rather than the heat content H . As a result the susceptibility would be independent of temperature. This picture implies that we must think of the dipoles in this case not as local elements embedded within the material matrix moving in a fixed local potential, but as an integral part of the matrix whose dynamics is described by fluctuations in the Gibbs free energy $G = H - TS$ of the whole ensemble. In this case correlations between dipoles would be expected to occur mainly via the indirect route through their interaction with their local environment, rather than their direct electrostatic interactions.

Equation (10.31) describes the behaviour of a system undergoing an order–disorder transition *among the permanent dipole orientations*. A similar behaviour will be found for the relaxation response of a first-order ferroelectric or dipole alignment transition [10.37]. In general phase transitions will not give rise to a divergence in χ_0 , which occurs because the phase transition in these cases is defined through the dipole, i. e. the dipole orientation is the order parameter. In other types of phase transition the dipoles are not the primary cause and what can be expected is an abrupt change of χ_0 as the dipoles find themselves embedded into a different lattice structure with different local potentials and orientation positions, different ensemble energies, and different correlations with one another and the material matrix.

The Information Content of the Dielectric Increment

As is clear from the above discussion it is not easy to make definite quantitative statements about the dipole system based on the dielectric increment. The basic reason for this situation is that the measurements are made on a macroscopic sample that contains an ensemble of an enormous number of dipoles, up to $\approx 10^{28} \text{ m}^{-3}$. The description of such systems can be carried through if the

elements, here electric dipoles, are independent and their orientation is defined by a static local potential; as discussed above this will not be the case in general. More typically the dipoles will be correlated with the matrix in which they are embedded and/or one another. This means that the dipoles that are involved in the dipole density fluctuations are not site dipoles but groups of molecules/ions including dipoles, i. e. the responding features have a size intermediate between that of the molecule/unit cell and that of the sample. Determination of the temperature dependence will give some clues as to how to regard the dipole system through the definition of an effective dipole. The way the effective dipole changes with temperature will allow some interpretation of the kind of system that is present. Variation with other control parameters will produce more information, and systematic variation of the structure, for example replacement of side groups in polymers by longer or different side groups, or substitution of impurity ions by similar ions of different oxidation state or ionic radius, will help to identify the local dipole moment contributing the dielectric increment. However, even if the form of the site dipole is known, the quantitative evaluation of a factor such as the Kirkwood factor g (10.32) is not trivial. In condensed matter, as can be seen from Fig. 10.7, only a component of the site dipole is likely to be involved in reorientation. Unless the local structure is very well known it will not be possible to determine the actual value of the reorientable component in order to obtain a quantitative estimate of g . What can be achieved is a fingerprint of the dipole fluctuations in the material that can be used to characterise it. However at best this will be a partial picture of the dipole fluctuations in the material and information gained from the relaxation time and the relaxation dynamics should be used to enhance it further. In this way a holistic view of the dipole fluctuation can be attempted. It is important to realise that the picture obtained from these three features must be complementary. It is not acceptable to regard them as three independent features, as in fact they just yield different facets of the same process.

10.3.2 The Characteristic Relaxation Time (Frequency)

Equation (10.14), (10.17), (10.22), and (10.23) define a characteristic relaxation rate γ or relaxation time $\tau = 1/\gamma$ for the dipole density fluctuations. In the case of the Debye response, whose susceptibility functions are given by (10.18) and (10.19), γ is the frequency at which the imaginary (dielectric loss) component $\chi''(\omega)$

exhibits a peak. It has therefore become customary to determine the dependence of the relaxation time (rate) upon the control parameters (e.g. temperature, pressure, etc.) that are varied via that of the loss peak frequency. As long as the frequency dependence of $\chi_r''(\omega)$ (i.e. the loss peak shape) remains unchanged this procedure is valid because essentially the dielectric response investigated can be treated as a single composite process, even though it has a wider frequency dependence than that predicted for the independent free dipoles. Both the theoretical equation of motion (10.22) and response function (10.26) do in fact describe the response as a single composite process with a characteristic relaxation rate (time). However the frequency of the peak in $\chi_r''(\omega)$ (loss peak frequency) predicted from (10.22) is not γ but γ multiplied by a numerical factor depending upon the power-law exponents, n and m . In many cases the loss peak is very broad ($n \rightarrow 1, m \rightarrow 0$) and it is difficult to locate the peak precisely and to be sure that the point located is at the same position with respect to the functional dependence of $\chi_r''(\omega)$ upon ω . Under these circumstances a better procedure is to construct a master curve, which is done by plotting $\chi_r''(\omega)$ as a function of ω in log-log coordinates. Translation of the data along the $\log(\omega)$ and $\log[\chi_r''(\omega)]$ axes will bring the data into coincidence if the susceptibility frequency dependence is unchanged. The translation required to achieve coincidence gives the dependence of the susceptibility increment [$\log(\chi'')$ -axis] and characteristic relaxation frequency [$\log(\omega)$ -axis] on the controlled variable. For example it gives the ratios $\gamma(T_1)/\gamma(T_2)$ [or $\chi_0(T_1)/\chi_0(T_2)$] for the temperature change T_1 to T_2 . This technique also has the advantage of illustrating clearly whether or not the frequency dependence is independent of the variation in temperature (or other parameter), i.e. whether or not the different sets of data can be brought into coincidence. It can also be used to determine any relationship between χ_0 and γ . This is done by selecting a reference point (e.g. the point $\chi_0 = A, \omega = B$) and marking the position on the master curve of this point from each data set after it has been translated to achieve coincidence. A trace is formed giving the dependence of $\log[(\chi_0)^{-1}]$ as a function of $\log(\gamma^{-1})$.

The relaxation rate is the dielectric response feature that shows most dependence upon the variation in the control parameters and so is the feature that is most often studied. In the following sections I will outline some of the most common types of behaviour and discuss their implications for the physics of the relaxation process.

Site Dipole Reorientation

The simplest form of relaxation rate is that described by Debye for independent molecular dipoles suspended in a viscous continuum. As described in Sect. 10.3.1 these dipoles are regarded as free to adopt any orientation in the absence of an electric field. Relaxation of a dipole density fluctuation involves the rotation of the molecular dipoles in the fluctuation to a state in which the net dipole density is zero. In such a situation the rotation of each individual dipole occurs at the same speed determined by the viscosity, η , of the medium, and the relaxation time ($\tau = 1/\gamma$) of the dipole density fluctuation is governed by that speed. For a molecular dipole whose effective length is a the relaxation time has the form [10.10],

$$\tau \propto \eta a^3 / k_B T. \quad (10.35)$$

The more viscous the medium, or the bigger the molecular dipole, the slower it rotates and the slower will be the relaxation of a fluctuation, giving a net dipole moment to the ensemble.

Of course the conditions for this behaviour to be exactly applicable cannot be met except in a gaseous medium. Condensed-phase materials are not continua. Even liquids possess a local structure and molecular dipoles will either be part of that structure if they are contributed by the medium, or will be surrounded by a solvent shell if they are dissolved in the medium. In solids the molecular (or ionic) dipole is of necessity part of the structural matrix, and even though this must be irregular enough to permit rotational displacement to at least one other orientation the matrix can be expected to maintain some structural correlation to distances well away from the site of a reorientable dipole. These are the conditions that must be included in any description of the relaxation frequency (time).

The first point of departure from the picture of a free dipole in a continuum is that the dipole will possess only a limited number of orientations that it can adopt. Consequently there will be a potential barrier between these alternative equilibrium orientations. The rate of transition between alternative orientations and hence the relaxation frequency will be determined by the rate at which a dipole or, to be more specific, the atoms or ions that form the local dipole can pass over the potential barrier to switch orientation, as shown for example in Fig. 10.7. In this case the relaxation frequency will possess an activated (Arrhenius) form where the activation energy Δ_γ is the mean potential barrier height between the alternative orientations, i.e.

$$\gamma = 1/\tau = A \exp(-\Delta_\gamma/k_B T). \quad (10.36)$$

The expression to be used for the pre-exponential factor A depends on the way in which the atoms/ions comprising the local dipole pass through the transition region at the top of the barrier [10.38, 39]. In the schematic drawing of Fig. 10.7 the dipole is described as having an atom (ion) at its head that performs quantum oscillations in one of two potential wells. As long as it can be assumed that there is a thermal equilibrium between all the vibration states and that the dipole head passes into the alternative well in a single transit of the barrier region, then $A = \nu$, where ν is the frequency of the quantum vibrations at the bottom of the wells. This result continues to hold even if thermal equilibrium is established only for the states at the bottom of the well as long as the effective friction acting on the dipole head in the barrier region is weak. The type of potential surface with these properties is one that remains essentially rigid during the actual transit of the barrier region, which takes place in a time typically of $\approx 10^{-14}$ s. The activated factor in (10.36) expresses the thermal probability of finding a dipole in a quantum state at the top of the barrier. The other extreme situation occurs when the friction ζ_d in the barrier region is high, for which $A \propto (1/\zeta_d)$. This occurs when the transit of the barrier region is slow enough to allow interactions with neighbouring vibrating atoms to overdamp the motion. In this case the potential surface distorts during the transit of the barrier. Such situations can be expected when the barrier is broad and ill-defined, and correspond to local structures that are flexible, such as may be expected in viscoelastic materials. A general expression $A = \lambda_r(\nu/\nu_b)$ has been developed by *Grote and Hynes* [10.39] where λ_r is a function that describes the change from low to high friction and ν_b is the quantum frequency in the barrier region.

An interesting consequence of this type of potential surface is that, regardless of the magnitude of the barrier energy Δ_γ , a temperature should exist below which reorientation over the barrier would take so long that any dipole fluctuation would essentially remain unrelaxed, i. e. the dipole system becomes frozen. However when the moving atom in the permanent dipole is a hydrogen atom this is not the case; relaxation can occur by the tunnelling of the hydrogen atom through the barrier [10.40]. This has been demonstrated by experiments on deuterated oxidised polyethylene molecules at millikelvin temperatures [10.41, 42]. In this case the relaxation frequency is determined by the tunnelling probability of the deuterium/hydrogen atom through the barrier, which is dependent upon the atomic mass, the barrier width and height, but *not the temperature*, i. e. the

relaxation frequency becomes temperature independent at temperatures below ≈ 100 mK.

Relaxation on a Free Energy Surface

The situation described in the previous section is one in which the dipole moves on a potential surface provided by the surrounding structural matrix. The only dynamic effect of the matrix is via elastic and inelastic interaction between the quantum vibrations of the dipole and the matrix. In many cases however, the atoms (ions) comprising the dipole will cause the displacement of the centres of motion of the surrounding atoms during its transit between alternative orientations. In this case the expression for the relaxation frequency has to refer to the group of atoms affected as a unit, and an appropriate form is that derived by *Eyring* [10.43] for chemical reactions

$$\gamma = (k_B T/h) \exp(-G^\# / k_B T). \quad (10.37)$$

Here $G^\#$ is the change in Gibbs free energy on passing from the ground state to the transition state in the process of reorientation. The barrier is now a free energy rather than a potential barrier and reflects the need for the involvement of displacements in a number of atoms, ions or molecules in order to achieve the dipole reorientation. If we refer again to Fig. 10.7 the difference is that the normal coordinate of the quantum vibrations in the barrier region is a mixture of several different normal coordinates of the surrounding matrix as well as that of the dipole in the well. In general $G^\#$ will be composed of an activation entropy contribution $S^\#$ as well as an activation enthalpy contribution $H^\#$ with $G^\# = H^\# - TS^\#$, and both will be properties of the group of atoms/molecules involved and their structural relationship. The expression for γ therefore takes a form similar to that of (10.36):

$$\begin{aligned} \gamma &= \left[(k_B T/h) \exp(S^\# / k) \right] \exp(-H^\# / k_B T) \\ &= A_{\text{eff}} \exp(-H^\# / k_B T). \end{aligned} \quad (10.38)$$

The activation entropy $S^\#$ will reflect the configuration rearrangement required for the dipole to reorient. Thus for example, when reorientation requires the surrounding matrix to adopt a more irregular (disordered) arrangement so as to remove a steric hindrance to reorientation the transition region entropy will be greater than that of the dipole in the bottom of the well and $S^\#$ will be positive. Alternatively the transition region may require specific local arrangements in order that the dipole can avoid such hindrances. In this case the entropy of the transition state will be less than that of the

dipole in the bottom of the well and $S^\#$ will be negative. A nonzero value of $S^\#$ will therefore lead to a relaxation frequency with an effective pre-exponential factor, A_{eff} , that is either greater or less than $k_B T/h$.

An interesting variation on this behaviour has been suggested by Hill and Dissado [10.44] who showed that several experimental relaxation frequencies could be described via what they termed an activated tunnelling expression. Here they allowed the possibility that the transfer between alternative orientations could take place by thermal activation to an energy state for which the tunnelling of hydrogen atoms through the barrier was feasible. An expression for the relaxation frequency was obtained by determining the optimum transfer rate, with all processes considered from that of an unactivated quantum tunnelling to activation over the top of the barrier. If the energy difference between the alternative orientations is zero the resulting relaxation frequency had the form

$$\gamma \propto \exp(BT) \quad (10.39)$$

over a considerable temperature range, where B is a temperature-independent factor dependent upon the tunnelling distance, the barrier height and shape, and the mass of the tunnelling particle. If the *barrier* in this work is taken to be a free-energy barrier rather than a potential barrier, the analysis can be seen to be equivalent to a situation whereby the dipole relaxes by finding a route between the alternative orientations that allows for lower values of $H^\#$ at the expense of ordering the surrounding molecules/atoms, i. e. a negative $S^\#$. Routes with higher values of $H^\#$ require values of $S^\#$ that are less negative. In this case the optimum relaxation frequency will take a form such as (10.39) and only at very high temperatures will γ become purely activated with $S^\# \approx 0$. The picture of dielectric relaxation provided by this interpretation is consistent with the *defect diffusion* mechanism [10.45], in which defects diffusing in the structural matrix, such as a kink in a polymer chain or a dislocation in a crystal, lower or remove barriers when they reach a dipole, allowing it to take an alternative orientation of equal energy. When the defect moves on, the dipole is locked into the new position until another defect arrives.

The Glass Transition

A glass is essentially a material that has become macroscopically rigid without attaining its thermodynamically favoured crystalline state. The manner in which this occurs for a liquid or viscoelastic (rubbery) material that has been rapidly cooled has been the subject of in-

tense investigation over a large number of years (see Angell [10.46]). A simple, some would say oversimple, view of the situation is to regard it as a concatenation of two effects. In the first place supercooling the liquid phase will at some temperature result in a situation where the liquid no longer possesses a heat content in excess of the crystal state at that temperature [10.47]. The liquid will be unstable with respect to a disordered solid possessing only local crystalline order. In the second place the lowering of the temperature during the supercooling will cause the lattice to contract thereby introducing and increasing barriers to local molecular/atomic motions. At some temperature the thermal fluctuations [described by the Boltzman factor in (10.36), (10.37)] that are responsible for raising the site energy to that of the barrier become so rare that the time required for rearrangement becomes enormously long. At this temperature, termed T_g , the structure is essentially locked into a macroscopically rigid state, termed a glass. The glass transition cannot be regarded as a thermodynamic transition of state (unlike a melting/crystallisation temperature for example) and there are different ways of defining and determining T_g (see [10.46]).

During the approach to the glass state the rate of reorientation of permanent dipoles will become slower and eventually reach zero as shown in Fig. 10.8. It is common to denote the response due to a set of dipoles that are frozen during glass formation as the α -response. A second response can be seen in the figure: termed the β -response. This is provided by dipoles that are able to reorient without requiring any substantial rearrange-

Fig. 10.8 The Arrhenius plot of the glass-forming polyvinylchloride system showing the slowing down of the α -response ($T > T_g$) as T_g is approached and the activated β -response. After [10.8]

ment of the surrounding structural matrix. It should not be expected however that this response is due just to a dipole reorientation with respect to the molecule it is attached to. In many cases the β -response involves the displacement of the molecule or part thereof as a whole [10.48]. In polymers this is a local *inter-chain* motion and either the free-energy expression (10.38) or the potential-energy expression (10.36) will apply, depending on whether the surrounding chains remain rigid during the relaxation or rearrange locally. These dipoles are active in the glass state and can be expected to have a relaxation rate of the form of (10.36), i. e. reorientation over a potential barrier. In the case of the α -response it is clear that the relaxations must involve displacements in a number of molecules/atoms other than just those comprising the permanent dipole, and hence it is instructive to discuss the behaviour in terms of the rate expression (10.37). What can be seen is that, as the temperature at which the system becomes rigid is approached, the gradient in the Arrhenius plot gets steeper, and $H^\#$ therefore becomes larger. The non-thermally-activated pre-exponential factor, A_{eff} , in (10.36) is greater than $k_B T/h$ and hence $S^\# > 0$. As the temperature approaches T_g there is an increase in A_{eff} , by many decades in frequency, which must be due to an increase in $S^\#$. These changes in $H^\#$ and $S^\#$ indicate that, as T_g is approached, dipole-orientation relaxation not only requires an increased amount of energy in order to enter the transition (barrier) region but also a larger amount of configuration disordering in the surrounding structure that makes up the molecular/atom group involved in relaxation. Although it is possible that such a situation may come about because reducing the temperature produces a local increase in density that increases steric hindrances for the same group of atoms and molecules, it is more likely that the number of molecules that are displaced in order to allow the dipole to pass through the transition region has increased. These considerations are consistent with a structure that is becoming either tangled or interlocked as the temperature decreases. Detailed expressions based on these concepts but involving macroscopic parameters have been attempted (see for example [10.46, 49–52]).

The glass formation discussed above has a structural basis and dipole–dipole interactions will play at most a minimal role. In some situations however, the glass is a disordered array of dipole orientations [10.30]. This sort of state is most likely to occur at very low temperatures in materials that possess dipoles occupying the sites of a regular lattice. At high temperatures the dipole orientations will be disordered but, as the temperature is reduced to low values, each individual

dipole would be expected to adopt their lowest-energy orientation, resulting in a state of ordered dipole orientation. A *dipole glass* will result instead when the dipole–dipole interactions produce forces that generate barriers to the local reorientation and frustrate the ordering process at temperatures low enough that the barriers generated cannot be overcome in any conceivable time.

Ferroelectric Transition

The dielectric response of ferroelectrics at temperatures in the vicinity of their Curie (critical) temperature also exhibit relaxation frequencies that approach zero, just as their dielectric increment approaches infinity (Fig. 10.9a,b) as discussed in Sect. 10.3.1. In this case both the dielectric increment and the relaxation frequency are functions of a hidden variable that characterises the system, the correlation length ξ of the dipole fluctuations. Just as the dielectric increment increases with a power of the correlation length, the relaxation frequency will decrease. Put simply the more dipoles are correlated in the fluctuation the longer the time that is required for its relaxation. Scaling theory [10.33] describes the system by a hierarchy of self-similar correlations. The strongest correlations are between the dipole and its nearest neighbours. This gives a local geometrical arrangement of correlations. The next-strongest correlations are between the same geometrical arrangement of groups of nearest neighbours, and the next strongest is between the same geometry of groups of groups. Eventually the whole system up to the correlation length is constructed in this way. Because the geometrical arrangement is preserved at each stage the properties for each stage have to be proportional to a power of the size. This gives

$$\gamma \propto |(T - T_c)|^\beta \propto \xi^{-\beta/\delta} \quad (10.40)$$

and using (10.31) the relationship

$$\chi_0 \propto (\gamma)^{-\alpha/\beta} \quad (10.41)$$

follows. But the theory can go further and predict the frequency dependence of $\chi_r''(\omega)$ and $\chi_r'(\omega)$ for $\omega > \gamma$. This follows because we can think of the response of the system to a field of frequency ω as being due to the correlation scale that can relax at the frequency ω , i. e. $\xi_\omega \propto \omega^{-\delta/\beta}$. The dielectric increment appropriate to this length scale can be obtained from (10.31) as $(\xi_\omega)^{\alpha/\delta}$ and hence,

$$\chi_r''(\omega) \propto \chi_r'(\omega) \propto (\xi_\omega)^{\alpha/\delta} \propto \omega^{-\alpha/\beta} = \omega^{n-1} \quad (10.42)$$

with $n = 1 - \alpha/\beta$. These relationships describe what is called dynamic scaling. A detailed description of the derivation of the frequency dependence in (10.42) is given in [10.33] and the relationship of the power-law frequency dependence to self-similar relaxations is shown explicitly using scaled electrical circuits in [10.53]. Because of the small range of temperatures around T_c over which the power-law relationships (10.40, 10.41) are expected to hold it is difficult to determine the exponents α and β with any

accuracy, however the dynamic scaling law can be easily demonstrated by using the master-curve technique and determining the locus of the representative point (see the beginning of Sect. 10.3.2). An example is shown in Fig. 10.9c where it can be seen that the representative-point locus of χ_0 as a function of γ is a power law with the same exponent as that of the frequency dependence of $\chi''(\omega)$ and $\chi'_t(\omega)$ for $\omega > \gamma$.

The Information Content of the Relaxation Frequency (Time)

The typical starting point in investigating the relaxation frequency (time) is to make an Arrhenius plot, i. e. $\log(\gamma)$ is plotted as a function of $1/T$. A straight line is taken to indicate an activated process of the form of (10.36), with the gradient yielding the activation energy $\Delta\gamma$. However in most cases data is only available from a restricted temperature range and so the variation of $k_B T/h$ with temperature will be small. In this case the free energy expression (10.38) would give an equally good straight line. Since there are many situations in which the pre-exponential factor in (10.36) will be less than a quantum vibration frequency $10^{12} \text{ Hz} \leq \nu \leq 3 \times 10^{13} \text{ Hz}$, it is difficult to discriminate between the potential-barrier situation and the free-energy barrier in which $S^\ddagger < 0$. Only when $A \gg 3 \times 10^{13} \text{ Hz}$ will identification with relaxation via a free-energy barrier be certain. As can be seen from the foregoing it is difficult to obtain any definite information from the pre-exponential factor in an activated relaxation, except for the latter case where an evaluation of S^\ddagger is possible. Where S^\ddagger can be determined it gives us a qualitative picture of a relaxing dipole centre which has to be structurally distorted in order for the dipole to adopt a different orientation. The corresponding value of H^\ddagger gives the amount of energy that has to be supplied to the group in order for the reorientation to occur even allowing for the distortion. What cannot be determined from this information is the size of the group that is involved, though the behaviour and magnitude of χ_0 may give an idea as to the dipole magnitude and density. To give an idea of the difficulty of a molecular interpretation let us take the case of cyclo-hexanol [10.54]. This molecule forms a plastic crystal, i. e. the molecular centres are located on a crystal lattice but their orientations are disordered. The dipole moment is associated with the only strong polar feature, the alcohol ($-\text{OH}$) group, which can take one of two orientations with respect to the molecule. It would therefore be expected that the measured activation energy of $\approx 0.5 \text{ eV}$ would be the potential barrier to the transfer of the alcohol group between the two positions, with its contributions from the neigh-

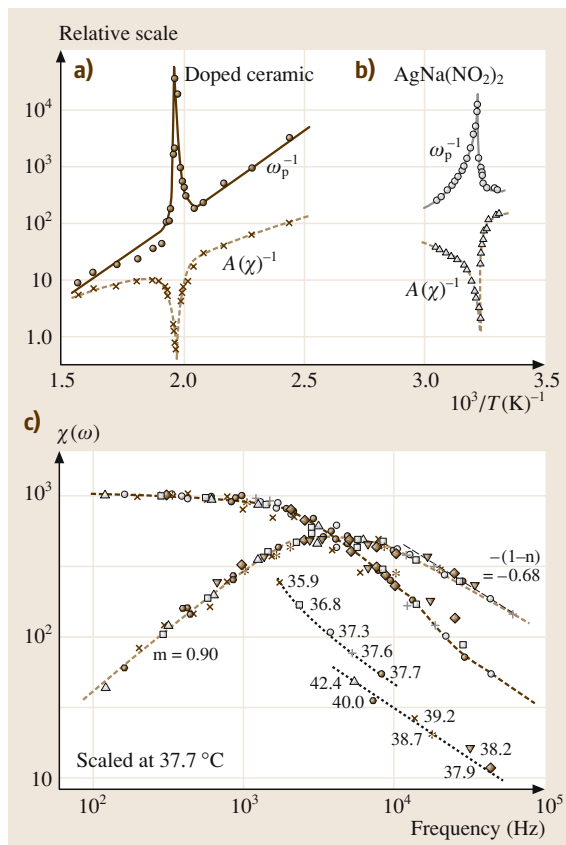

Fig. 10.9a–c An Arrhenius plot of the inverse of the susceptibility increment $A(\chi)(\equiv \chi_0)$ and loss peak frequency $\omega_p(\equiv \gamma)$ is shown for (a) a ceramic and (b) $\text{AgNa}(\text{NO}_2)_2$. The frequency-dependent susceptibility of $\text{AgNa}(\text{NO}_2)_2$ is shown in (c) together with the locus of the representative point as $T_c = 37.8^\circ\text{C}$ is approached from above and below. Note the power-law relationship between the dielectric increment and the relaxation frequency, and the parallelism between this locus and the frequency dependence at $\omega > \gamma$, demonstrating an identical power-law behaviour. After [10.35]

bouring molecular cage as well as the molecular energy change. However, the molecular structure of the cyclohexanol can itself exist in two conformations, the chair and the boat, and can rearrange its orientation in a lattice by passing through the alternative conformation as an intermediate. The free-energy barrier to this interconversion is also ≈ 0.5 eV. So we cannot decide from the relaxation frequency whether the relaxation involves just —OH group transfer or transfer via a boat-to-chair transition or a mixture of both. In this case the pre-exponential frequency $A_{\text{eff}} \approx 6 \times 10^{16}$ Hz, so relaxation has to have a positive S^\ddagger and involve a number of atoms rather than a dipole reorienting on a rigid potential surface.

In the case of near-crystalline materials where the dipole is associated with defect centres we would expect the potential-barrier approach to be the best, but even here the fact that local reorientation is possible implies some sort of interaction between the surroundings and the moving dipole head. Calculations based on a rigid cage should (see for example [10.55]) however be possible, and comparison with experiment can be expected to determine how well this represents the situation and to what extent the transit of the barrier is affected by the barrier friction. Information provided by the dielectric increment should be of help here. The calculation ought to be able to yield an estimate of the reorientable component of the dipole, and if as seems likely the alternative orientations are at different energies, the temperature dependence of χ_0 should follow (10.34).

Although it is conceptually simple to think of dipoles relaxing upon a potential surface that remains unchanged during the relaxation, this is likely to be only an approximation to reality. The fact that alternative orientations exist indicates that in most cases the surrounding structure must be modified to some extent to accommodate the change; at the very least we can expect the dipole to polarise its surroundings differently according to its orientation. The expressions in Sect. 10.3.2 for the relaxation frequency of dipoles relaxing on a free-energy surface and dipoles in ferroelectrics reflect this fact in different ways. The ferroelectric behaviour described in Sect. 10.3.2 shows that when the *dipoles* become extensively correlated the relaxation frequency reduces as an inverse power of the correlation length and the dielectric increment increases as a power of the relaxation length. The self-similar scaling relates this behaviour to the frequency dependence of the susceptibility. The behaviour of the α -response of a glass-forming system involves dipole–structure interaction in a different way. The relaxation frequency approaches zero as T approaches T_g from above. Whatever the details of

the process this behaviour has to indicate an increased difficulty for the dipole to reorient, which here is associated with structural ordering, densification, and atomic packing, rather than long-range correlations as in ferroelectrics. This response is also one for which the dielectric increment is often insensitive to temperature. If we put the two dielectric response features together we come to a picture in which the electric field effectively modifies the configuration entropy of the system in generating a net dipole density fluctuation. The net dipole density produced is essentially the same at different temperatures, so the change in configuration density generated by the electric field does not vary, but the relaxation time increases as the activation enthalpy H^\ddagger and entropy S^\ddagger increases. Put together with the fact that in structural glass formation small local regions are attempting to adopt a crystalline structure, this data indicates that there are *local* values of ground-state configuration entropy that reduce as T_g is approached, with a transition state involving a disordering of the local regions to free the dipole enough to let it adopt an alternative orientation in an equally ordered but different configuration. The dipole density fluctuations that couple to the electric field seem to involve reorganisations of the structure that can occur without a change in the value of the heat content H , i.e. they are essentially configuration entropy fluctuations rather than thermal fluctuations. In contrast to the ferroelectric situation the slowing down of the relaxation is not caused by longer-range correlations but by the increasingly larger numbers of molecular adjustments required to achieve a dipole reorientation.

The message of this section is that in most cases a detailed molecular description of the dipole motions is generally not accessible just from an analysis of the dielectric response. The reason is that, in general, dipole reorientations involve adjustments in the surrounding molecules/atoms that are not easy to define in molecular terms. However by putting together the behaviour of the dielectric increment and relaxation frequency it should be possible to obtain some general idea as to the extent of the connection of the reorientation to the molecular environment and the way in which it takes place.

10.3.3 The Relaxation Peak Shape

The explanation of the frequency dependence of the susceptibility is currently the most contentious of the features of the dielectric response. Many workers are content with just defining the shape by one or other of the empirical functions mentioned in Sect. 10.2.2, or

through the power-law exponents of (10.20, 10.21). This gives a fingerprint of the dipole dynamics but no more. In particular it does not provide a description of the equation of motion of the dipole density fluctuation. Others determine what is termed a *distribution of relaxation times* for the loss peak in $\chi_r''(\omega)$. Essentially this approach is predicated on the assumption that the broadening of the loss peak compared to that of the Debye response (10.19) is the result of dipoles of the same type and dipole moment that each relax according to the Debye equation of motion (10.17) but possess different relaxation times with a distribution denoted by $g(\tau)$, which is defined via (10.43)

$$\chi_r''(\omega) = \int_0^{\infty} g(\tau) \frac{\chi_0 \omega \tau}{1 + \omega^2 \tau^2} d\tau. \quad (10.43)$$

This construction is still no more than a fingerprint unless a physical reason for the distribution $g(\tau)$ can be found. Usually this is ascribed to a distribution of local activation energies associated with dipoles that each exist in their own potential surface independent of one another. The system usually quoted as an example is that of the β -response in the rigid glassy phase, which typically has a very broad loss peak. In this case it is assumed that each dipole that can reorient to contribute to the β -response is essentially trapped in a local potential surface that is held rigid in the glass state. Of course the potential surface is not truly rigid, molecular/atomic vibrations must take place, but it is assumed that their effect on the potential averages out during the relaxation and their only effect is to raise the energy state of the reorienting dipole head to the state at the top of the barrier. One problem associated with this explanation of the origin of $g(\tau)$ is that, if the function $g(\tau)$ is independent of temperature the values of exponents n and m (10.20), (10.21) will be temperature dependent. This does not seem to be the case in general, with these exponents usually either constant or changing at the most slowly or discretely at a transition of state (see for example [10.8, 56]), but there is no real agreement on this point. Of course a temperature-dependent distribution function $g(\tau)$ may be assumed, but then the question arises as to why it is temperature dependent in a system that is presumed to be macroscopically rigid. Another facet of the problem associated with non-Debye loss peaks that does not seem to have received any consideration is the possibility that the magnitude of the reorientable dipole moment associated with each site of a given activation energy is also distributed. It is clear that this is highly likely even if the dipole mo-

ment that changes direction is the same everywhere, as illustrated in Fig. 10.7. Also, as described in Sects. 10.2 and 10.3, the local dipole may be correlated with other dipoles or its surroundings, and in this case we can expect the Debye rate equation not to hold. The ferroelectric result (Sect. 10.3.2) already shows that this is the case when the dipoles motions are correlated giving the system a scale relationship in its dynamics, and even correlation between the dipole and its surroundings, for which there is considerable evidence (Sects. 10.2 and 10.3) can be expected to alter the form of the equation of motion from (10.17), by for example anharmonic coupling between the various modes. Even if we assume that all the criteria for the application of (10.43) are met, the $g(\tau)$ that are required to fit the experimental form of response defined by (10.20), (10.21) [and its corresponding theoretical response function, (10.22)] have unique features that require a physical justification, i. e. there is a cusp or sharp peak at the value of τ corresponding to the characteristic frequency ($\tau_c = 1/\gamma$), and power-law wings to either side whose power exponents are $1 - n[g(\tau) \propto \tau^{1-n}]$ for $\tau < \tau_c$, and $-m[g(\tau) \propto \tau^{-m}]$ for $\tau > \tau_c$. In the Debye case the distribution becomes a delta function at the characteristic relaxation time. Essentially the *distribution of relaxation times* approach is convenient but it is not as easy to justify as would seem at first sight.

The Williams and Watt response function [10.28] started life as a heuristic suggestion but has received some later theoretical support [10.57–62]. The dynamic scaling behaviour appropriate to ferroelectrics gives a clue as to the way in which a frequency-dependent susceptibility of the form of (10.20) can come about, which results from both the equation of motion (10.22) and the response function (10.26). Essentially there has to be a self-similarity (or scaling) between the relaxation frequency of subcomponents of the system and their contribution to the dielectric increment (as illustrated in the circuit model of [10.8]). The theory proposed by Palmer et al. [10.60] refers this scaling to the removal of a hierarchy of constraints, thus for example we may imagine that close neighbours move quickest and remove the constraints imposed on larger groups of molecules and so on. This picture would be appropriate to a system such as a glass-forming material. The assumption however is that the motions are overdamped at all levels of the hierarchy, and hence no bridge is provided to the oscillatory motions known to occur at times close to quantum vibrations. A rather different stochastic approach has been taken by Weron and Jurlewicz [10.61, 62] who assumed that the system re-

relaxation followed a path in which the fastest dipoles out of a distribution relaxed first and then the fastest out of the residual distribution and so on. The key feature is that the relaxing dipole is the extreme fastest from the distribution existing at the time. It was argued that the extreme-value statistical distribution function then led automatically to the response function of (10.26). The choice of appropriate extreme-value distribution was made on the grounds that the relaxation time was a positive definite variable. However this is not a sufficient criterion [10.63]. In order for (10.26) to apply the continuous distribution density of relaxation times (i.e. the distribution the system would have if it were of infinite size) has to be stable to scale changes (see for example [10.64]) and thus has to approach the extreme of long times as an inverse power law, otherwise a different extreme value statistic or *none at all* applies. The required form of distribution from which an extreme selection has to be made is one that applies to the size distribution of scaling systems [10.65] such as percolation clusters [10.66] for example. So even with this stochastic approach we are led back to a system for which the dynamics scale in some way.

The Dissado–Hill function [10.23, 24] for which the response function obeys (10.22) also has scaling features as its basis, however unlike the other approaches it starts with the vibration dynamics of the system. It is assumed that a dipole that can reorient couples local vibration modes to itself. These are no longer extended normal modes but modes centred on the dipole that reduce in frequency according to the molecular mass involved. Their frequencies lie in the region between optical modes and the relaxation frequency and have a scaling relationship one to another. In the theory of Nigmatullin and Le Mehaute [10.67, 68], the modes are impulses that are involved in the dipole relaxation process whose time of action is scaled, i.e. the longer the time of action the more correlated they are to the dipole motion. In general these modes are local versions of coupled optical and acoustic modes and it is not surprising that they extend to such low frequencies as those involved in relaxation, as acoustic modes essentially extend to zero frequency. Their coupling with the dipole leads to the high-frequency power law of (10.20), where n expresses the extent to which the dipole reorientation couples to the surroundings, i.e. $n = 0$ corresponds to no coupling and the dipole moves independently of its surroundings, and $n = 1$ corresponds to full coupling in which the dipole motion is just part of the local mode. In a sense the short-time development of the response function of (10.22) is that of the changes in the con-

figuration entropy as various amounts of different local modes are progressively coupled into the dipole motion [10.23]. In this case there is no necessity for n to be temperature dependent. At the characteristic relaxation frequency, the *characteristic* dipole group relaxes and transfers energy to the heat bath. The low-frequency behaviour of (10.21) is the result of a distribution in the ensemble of locally coupled dipole motions. This occurs because the motions of local dipole centres may be weakly coupled to one another. As a result the relaxation of the centres proceeds in a scaled or self-similar manner. First the dipole in a local centre relaxes with respect to its own environment, this leaves each dipole centre unrelaxed with respect to one another. Next groups of dipole centres, with some arrangement depending upon the specific structure involved, relax as a group. Then groups of groups relax and so on. Each level of inter-group complexity essentially has a time scale associated with its relaxation that cannot be reached until the preceding level has been completed. This is rather similar to the constraint relaxation concept of Palmer et al. [10.60]. The power-law exponent m expresses the way that this hierarchy of relaxing groups is scaled, by defining the power-law tail of the distribution of inter-group relaxation times in the ensemble [10.69]. A value of $m = 1$ corresponds to a sequence of inter-group relaxations with a relaxation time that is proportional to the number of groups involved in the sequence [10.69]. This implies that the sequential events are uncorrelated, i.e. the long-time relaxation is a white-noise (random) process [10.23]. When combined together with $n = 0$ the Debye response is recovered. On the other hand a value of m approaching zero corresponds to relaxation times that are a very high power of the number of groups involved [10.69] and indicates a very strong connection between groups at all levels of the hierarchy. This will spread the response to very low frequencies, as observed. Essentially m is a measure of the extent to which energy is transferred to the heat bath (dissipated) at each level of the hierarchy compared to being stored in the inter-group interactions of the next level. Again scaling is at the basis of the theory, but now with two different ways in which it can be involved. This theory is not generally accepted. The controversial parts of the theory are firstly the coupling of the dipole motions with vibration modes, which modifies the oscillator behaviour towards an over-damped form, and secondly the hierarchy of relaxations whereby energy is transferred to the heat bath. However it should be noted that the susceptibility function that results has a general form that agrees well with experiment. In addition the concepts are reasonable given

the complexity that is likely to occur in the internal motions once an ideal crystalline regularity is ruled out by the possibility of dipole reorientation. Thus for example this concept would apply to the dipoles involved in the β -response of the glass state as well as correlated motions of dipoles over long distances, since even in a macroscopically rigid material local vibrations take place. In fact the limited regions of local order in a glass phase can be expected to favour such local modes and increase the coupling of the dipole motions with them, as observed.

The Information Content of the Loss Peak Shape

It is clear from the foregoing discussion that for all theoretical models of the loss peak shape the characteristic or loss peak frequency is but the culmination of a process in which subsections of the dipole and environment (with or without dipoles) are mixed into the motion of the dipole centre. In these models the dipole is not an independent entity, but rather an entity that is connected to some extent over a region that may be small or large. This implies that the dipole is not a particle that relaxes on a rigid potential surface independently of its environment. Only the *distribution of relaxation times* approach preserves the latter concept. If the theoretical models are correct they reflect the fact that we are looking at entities that are not truly of molecular scale but are of a mesoscopic nature. The correlations noted to occur in χ_0 and the need to use free energy rather than potential surfaces in describing the relaxation frequency

support this view. The local entities involved are however not rigid features like permanent dipoles, and for this reason we should expect there to be weak connections between them that can be expected to relate to the way in which the relaxation of the whole system takes place. That is, not all entities relax at the characteristic time. As one entity relaxes its neighbours have to come into equilibrium with its new orientation and the system approaches equilibrium more slowly [i.e. as the time power law $t^{-(1+m)}$] than the exponential behaviour of the Debye response function or the expanded exponential function. The information contained in the loss peak shape indicates the way in which a dipole density fluctuation evolves from its state when initially created to an ensemble of mesoscopic dipole centres. The broadening of the peak from that of a Debye peak indicates the involvement of faster and slower processes as part of the overall mechanism, whatever their detailed origin, and in particular processes that have a scale relationship to one another. This must apply even to a distribution of relaxation times because of the unique form required for that distribution. Equation (10.22) implies an equivalent description that refers the overall relaxation process to a conversion of the vibration oscillation at short times to an overdamped motion as the dipole density fluctuation dissipates its energy irreversibly. In this sense evaluation of the shape parameters n and m give a means of describing this conversion process. At the very least they give a sense of the scaling involved in spreading the relaxation process around the characteristic relaxation frequency or equivalently the characteristic relaxation time.

10.4 Charge Transport

All dielectrics possess a constant (DC) conductivity (σ_{DC}), although usually it is very weak. Since $\chi''(\omega) = \sigma(\omega)/\omega$ as demonstrated in Sect. 10.1 (10.10), it would be expected that a dielectric response at low frequencies ($f \lesssim 10^{-2}$ Hz) would take a form in which $\chi''(\omega) = \sigma_{DC}/\omega$ and χ' is independent of frequency. In many cases however the conduction process is blocked at the electrodes or internal interfaces. In this case the DC conduction charges the interface, which behaves as a capacitor, and the whole system behaves as a single dipole. As long as the interface does not possess relaxation dynamics of its own, the response that would be observed is that given by the Debye response of (10.18, 10.19), with $\tau = 1/\gamma = RC_i$, where R is the resistance of the body of the material and C_i is the

capacitance of the interface. The measured dielectric increment $\chi_0 = dC_i/A$, where A is the electrode area and d is the sample thickness, and can be very large depending upon the ratio of the sample thickness to that of the interface. The situation where the interface has a frequency-dependent capacitance has been thoroughly discussed by Jonscher [10.6] who has shown that $\chi_r'(\omega)$ is modified from $\chi_r'(\omega) \propto \omega^{-2}(\omega > \gamma)$ to $\chi_r'(\omega) \propto \omega^{-q}$, while $\chi_r''(\omega) \propto (1/\omega)(\omega > \gamma)$ as in (10.19). The value of q lies in the range $1 < q < 2$ with its value depending upon the frequency dependence of the interface capacitance.

The bulk DC conductance arises from charged particles whose movements are not bound to a charge of the opposite polarity as in dipoles but are free to

move independently of their countercharge, resulting in a net charge displacement in the same way that a liquid flows. However the transport of charged particles within the body of the sample can give rise to a very different form of response when their movement lies along defined paths such that the longer the displacement of the charge the lower the number of paths or equivalently the more difficult the transport becomes. This behaviour was called low-frequency dispersion by *Jonscher* [10.6, 20] and quasi-DC conduction (q-DC) in the theoretical model of *Dissado and Hill* [10.70] who wished to distinguish it from low-frequency dipole responses. At frequencies below some characteristic value ω_c this form of response takes the form,

$$\sigma(\omega) \propto \omega^{1-p}$$

$$\left[\text{i. e. } \chi_r''(\omega) \propto \chi_r'(\omega) \propto \omega^{-p} \right], \quad \omega < \omega_c \quad (10.44)$$

and at frequencies above ω_c ,

$$\sigma(\omega) \propto \omega^n$$

$$\left[\text{i. e. } \chi_r''(\omega) \propto \chi_r'(\omega) \propto \omega^{n-1} \right], \quad \omega > \omega_c. \quad (10.45)$$

The power-law exponents p in (10.44) and n in (10.45) have positive fractional values near to unity. It is obviously difficult to identify a value of p close to unity from measurements of $\chi_r''(\omega)$ [or equivalently $\sigma(\omega)$] and in many cases it is assumed that the measured behaviour shows a static (DC) conductivity. It is then common to subtract its supposed value from the measured data for $\sigma(\omega)$ to obtain an expression for the dipole relaxation response supposedly responsible for the behaviour at $\omega > \omega_c$. The values obtained in this way for $\chi_r''(\omega)$ at frequencies $\omega < \omega_c$ will not be zero as $\sigma(\omega)$ is not in fact constant, instead they will reduce as the frequency is reduced. This procedure yields a spurious loss peak in $\chi_r''(\omega)$ if the response is actually due to the q-DC mechanism, for which the high-frequency behaviour is an essential component of the whole q-DC mechanism and can never be resolved as a separate peak in $\chi_r''(\omega)$. The way to be certain that the response is really of the q-DC form is to measure the frequency response for $\chi_r'(\omega)$ and show that it takes the same frequency dependence. A convenient check is to determine the ratio of $\chi_r''(\omega)$ to $\chi_r'(\omega)$ (i. e. $\tan \delta$) which will have a constant value [10.6, 20] given by

$$\chi_r''(\omega)/\chi_r'(\omega) = \tan \delta = \cot[(1-p)\pi/2]. \quad (10.46)$$

Here $\tan \delta$ is called the loss tangent and δ is the phase angle between the real and imaginary components of the

susceptibility. This relationship holds for pairs of values of $\chi_r'(\omega)$ and $\chi_r''(\omega)$ at the same frequency even if the measurements are noisy and so make it difficult to determine accurately the value of p from the frequency dependence. Another situation where it is difficult to detect the q-DC behaviour occurs in heterogeneous materials when one component has a low DC conductivity. This will add to the AC component, (10.44) and obscure the q-DC behaviour. In this case the DC conductivity can be eliminated from the data, if it is available over a large enough frequency range, by applying the Kramers–Kronig transform of (10.25) to obtain the function $\chi_r''(\omega)$ without the DC component (σ_{DC}/ω). The validity of the procedure can be checked by applying the inverse transform (10.24) to the measured data for $\chi_r''(\omega)$. This should yield the measured $\chi_r'(\omega)$ since the DC conductivity does not contribute to the real component of the susceptibility.

The q-DC behaviour, (Fig. 10.10a), is most often found in materials that are heterogeneous on a mesoscopic scale such as ceramics [10.71], rocks [10.72], porous structures [10.73], and biological systems [10.74]. In these materials charged particles are transported via structured paths over some finite range. The transported charge and its countercharge give rise to an effective dipole with a large dipole moment. However the q-DC behaviour rarely appears as an isolated response. Because of the heterogeneous nature of the materials it is usually found to be electrically in series with other dielectric response elements such as interface capacitances, and electrically in parallel with a capacitive circuit element. The origin of the q-DC behaviour lies in a hidden scale relationship, with the dipole contribution to the susceptibility increment and its relaxation time both being a power of the length over which the transport takes place. The circuit models of *Dissado and Hill et al.* [10.8, 75] show how this behaviour can be produced when the system is represented by a geometrically self-similar arrangement of transport paths and blocking capacitive regions. Such geometrical regularity is not essential however [10.76]; a random arrangement of conductors (transport paths) in a dielectric (i. e. residual set of capacitances) will also result in the q-DC behaviour. It is clear that this construction yields percolation clusters below the size necessary to span the material, and these sub-percolation clusters will of necessity possess scaling relationships dependent on their size and the number of paths within them, and between clusters of different sizes. Such percolation systems also show q-DC behaviour when below their critical limit [10.77]. The theory proposed in [10.70]

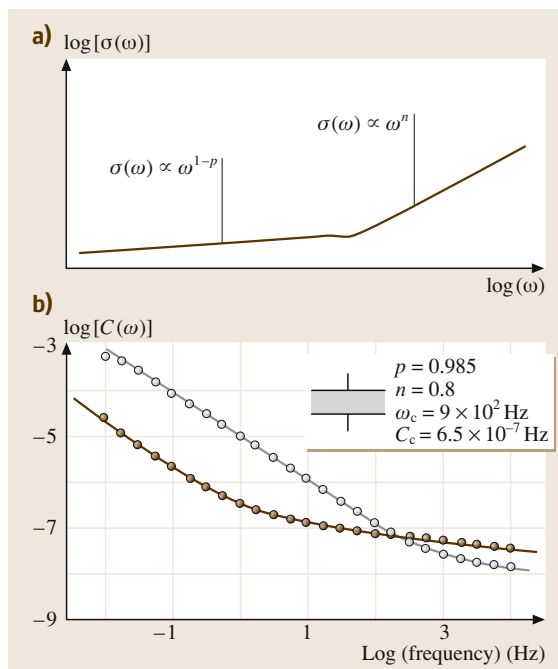

Fig. 10.10 (a) A schematic representation of the frequency dependence of $\sigma(\omega)$ for the q-DC process, (b) the equivalent q-DC susceptibility function $\chi(\omega)/\chi_c \propto (1 + i\omega\tau)^{n-1} {}_2F_1[1-n; 1+p; 2-n; (1+i\omega\tau)^{-1}]$ derived from the response function of (10.47) fitted to data from the leaf of *Nicotiana* (Solanaceae), the inset gives the fitting parameters, with $\omega_c \equiv 1/\tau$, and $C_c \equiv \chi_c$. This data was chosen as it exhibits an isolated q-DC process. As before ${}_2F_1(\cdot; \cdot)$ is the Gaussian hypergeometric function; see [10.25]. After [10.79]

described the q-DC mechanism in similar terms to that used in percolation theory. At high frequencies they assumed that the charged particles had a short range of motion restricted to local clusters in which they were bound to their countercharges. The power-law exponent n reflected the extent of binding of the motions of the charges in the cluster and the local motions in the same way as for the dipole motions. Its value close to one indicates that the binding is strong and that the polarisation of the local clusters increases only to a small extent as the frequency is lowered, i.e. the net displacement of positive and negative charge is local and small. At the characteristic frequency the charged particles become free of their locality and are able to move

over much longer distances. The range allowed by the AC frequency increases as the frequency reduces, but the number of effective routes decreases as the distance becomes longer and hence the current becomes smaller. This leads to the weak dependence of the conductivity upon the AC frequency defined in (10.44). In the zero-frequency limit $\sigma(\omega) = 0$, which means that there are no paths across a system of infinite length, i.e. the system is formally below the percolation limit. Of course in reality the sample is of finite size and some routes may cross the sample, leading to a termination of the q-DC behaviour at low frequencies, either by a blocking capacitance at the electrodes or a weak DC current [10.78]. The theory leads to an analytical expression for the q-DC susceptibility in terms of a confluent hypergeometric function [10.25] (see [10.70] for the detailed expression), which is obtained from a response function that obeys an equation of motion similar to that of the permanent dipoles

$$\frac{d^2\phi}{dt^2} + \frac{(2+n+t/\tau)}{t} \frac{d\phi}{dt} + \frac{[n+(t/\tau)(1-p)]}{t^2} \phi = 0. \quad (10.47)$$

At times $t < \tau = 1/\omega_c$ the behaviour of the dipole density fluctuation is the same as that appropriate for permanent dipoles (10.22) with the same limiting solution, i.e. $\phi(t) \propto t^{-n}$ at $t < \tau$. At long times $t > \tau = 1/\omega_c$, however, it takes a different form in which the dipolar fluctuation relaxation has only a weak dependence on t , i.e. $\phi(t) \propto t^{p-1}$ at $t > \tau$. An example of the q-DC behaviour in frequency is given in Fig. 10.10b. The reader is referred to [10.74, 79, 80] for other examples.

In the limit of $p = 1$ [$\sigma(\omega) = \text{constant}$; $\omega < \omega_c$], the last term of (10.47) is zero in the limit $t > \tau$ at which time the decay of ϕ is governed by the first two terms. The solution for $\phi(t)$ now takes the form

$$\begin{aligned} \phi(t) &\propto t^{-n}, & t < \tau, \\ \phi(t) &\propto \exp(-t/\tau), & t > \tau. \end{aligned} \quad (10.48)$$

In this case we can see that the dipole density fluctuations are produced within the local clusters and that they relax by freeing the charges to move independently at $t = \tau$. At this time there is a density of completely free charged particles with charge and countercharge cancelling throughout the system giving a net dipole of zero as in a true DC-conduction process.

10.5 A Few Final Comments

The basic difficulty associated with the interpretation of dielectric responses is that they are of necessity macroscopic measurements made on samples that contain enormous numbers of atoms and molecules. In condensed-phase materials it is not possible to consider these systems as made up of local entities each moving independently of one another. All entities that contribute a permanent dipole are part of the condensed-phase structure, and even though they have a degree of freedom associated with the possibility of dipole reorientation, they will have motions that are correlated or connected to some extent to the molecules/atoms in their environment. This means that dipole reorientation is not that of a bare entity; instead it involves to some extent a local region. These regions will behave differently in different kinds of material and their definition and the way of describing their behaviour has not yet been established with any sort of rigour. Since we are dealing

with a macroscopic measurement, there will of necessity be an ensemble of the local entities. This will result in a distribution of entities, but since these are part of the structure there will be some sort of connection between them unless the structure itself is disconnected dynamically. This means that fluctuations will take place among our entities, and perhaps even dissociation and amalgamation. These effects will also have an influence on the relaxation dynamics. In the foregoing I have tried to give some simple pictures as to what is happening and to do so in a holistic way by correlating information from different facets of the measurement. What is abundantly clear is that the dynamics of such systems are very complicated in detail, but I hope that I have done enough to convince you that there are some basic features of the relaxation process that are common to all systems of this type, even though a full understanding of their nature does not yet exist.

11. Ionic Conduction and Applications

Solid state ionic conductors are crucial to a number of major technological developments, notably in the domains of energy storage and conversion and in environmental monitoring (such as battery, fuel cell and sensor technologies). Solid state ionic membranes based on *fast ion conductors* potentially provide important advantages over liquid electrolytes, including the elimination of sealing problems and the ability to miniaturize electrochemical devices using thin films. This chapter reviews methods of optimizing ionic conduction in solids and controlling the ratio of ionic to electronic conductivity in mixed conductors. Materials are distinguished based on whether they are characterized by intrinsic vs. extrinsic disorder, amorphous vs. crystalline structure, bulk vs. interfacial control, cation vs. anion conduction and ionic vs. mixed ionic–electronic conduction. Data for representative conductors are tabulated.

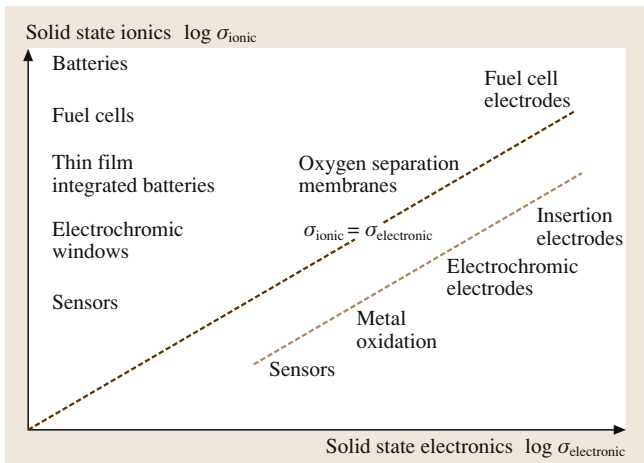

A number of applications that rely on solid state electrolytes and/or mixed ionic–electronic conductors are considered, and the criteria used to choose such materials are reviewed. Emphasis is placed on fuel cells, sensors and batteries,

The ionic bonding of many refractory compounds allows for ionic diffusion and correspondingly, under the influence of an electric field, ionic conduction. This contribution, for many years, was ignored as being inconsequential. However, over the past three to four decades, an increasing number of solids that support anomalously high levels of ionic conductivity have been identified. Indeed, some solids exhibit levels of ionic conductivity comparable to those of liquids. Such materials are termed *fast ion conductors*. Like solid state electronics, progress in *solid state ionics* has been driven by major technological developments, notably in the domains of energy storage and conversion and environmental monitoring, based on ongoing developments in battery, fuel cell and sensor technologies. Some of the most important applications of solid state electron-

where there is strong scientific and technological interest. The chapter concludes by considering how solid state ionic materials are likely to be used in the future, particularly in light of the trend for miniaturizing sensors and power sources.

ics and solid state ionics, and their categorization by type and magnitude of conductivity (such as dielectric, semiconducting, metallic and superconducting), are illustrated in Fig. 11.1 [11.1]. This figure also emphasizes that solids need not be strictly ionic or electronic, but may and often do exhibit mixed ionic–electronic conductivity. These *mixed conductors* play a critical role – particularly as electrodes – in solid state ionics, and are receiving comparable if not more attention than solid electrolytes at the present. Such solids are the result of a combination of the fields of *solid state ionics* and *solid state electrochemistry*, and they have grown in importance as our society has become more acutely concerned with efficient and environmentally clean methods for energy conversion, conservation and storage [11.2].

Solid state ionic membranes provide important potential advantages over liquids. The most important of these include: (a) elimination of sealing problems

11.1 Conduction in Ionic Solids

The electrical conductivity, σ , the proportionality constant between the current density j and the electric field E , is given by

$$j/E = \sigma = \sum_i c_i Z_i q \mu_i \quad (11.1)$$

where c_i is the carrier density (number/cm³), μ_i the mobility (cm²/Vs), and $Z_i q$ the charge ($q = 1.6 \times 10^{-19}$ C) of the i th charge carrier. The huge (many orders of magnitude) differences in σ between metals, semiconductors and insulators generally result from differences in c rather than μ . On the other hand, the higher conductivities of electronic versus ionic conductors are generally due to the much higher mobilities of electronic versus ionic species [11.3].

Optimized ionic conduction is a well-known characteristic of molten salts and aqueous electrolytes wherein all ions move with little hindrance within their surroundings. This leads to ionic conductivities as high as 10^{-1} – 10^1 S/cm in molten salts at temperatures of 400–900 °C [11.4]. Typical ionic solids, in contrast, possess limited numbers of mobile ions, hindered in their motion by virtue of being trapped in relatively stable potential wells. Ionic conduction in such solids easily falls below 10^{-10} S/cm for temperatures between room temperature and 200 °C. In the following sections, we examine the circumstances under which the magnitude

Fig. 11.1 Illustration of typical applications of ionic and electronic conductors as a function of the magnitude of electrical conductivity. Applications requiring mixed ionic electronic conductivity fall within the quadrant bounded by the two axes. After [11.1]

associated with chemically reactive liquid or molten electrolytes; (b) minimization of discharge under open circuit conditions, and; (c) the ability to miniaturize electrochemical devices through the use of thin films. In the following, we begin by discussing methods of optimizing ionic conduction in solids and controlling the ratio of ionic to electronic conductivity. We then consider a number of applications that rely on solid state electrolytes and/or mixed ionic–electronic conductors and the criteria that should be used when selecting materials. We conclude by considering how solid state ionic materials are likely to be used in the future, particularly in light of trends related to the miniaturization of sensors and power sources.

of ionic conduction in solids approaches that found in liquid electrolytes.

The motion of ions is described by an activated jump process, for which the diffusion coefficient is given by [11.5]

$$\begin{aligned} D &= D_0 \exp(-\Delta G/kT) \\ &= \gamma(1-c)Za^2v_0 \exp(\Delta S/k) \exp(-E_m/kT), \end{aligned} \quad (11.2)$$

where a is the jump distance, v_0 the attempt frequency, and E_m the migration energy. The factor $(1-c)Z$ defines the number of neighboring unoccupied sites, while γ includes geometric and correlation factors. Note that the fractional occupation c here should not be confused with c_i , the charge carrier concentration, nor should the number of nearest neighbors Z be confused with Z_i , the number of charges per carrier defined in (11.1). Since the ion mobility is defined by $\mu_i = Z_i q D_i / k_B T$, where D_i and k_B are the diffusivity and Boltzmann constant respectively, and the density of carriers of charge $Z_i q$ is Nc , where N is the density of ion sites in the sublattice of interest, the ionic conductivity becomes

$$\begin{aligned} \sigma_{\text{ion}} &= \gamma \left[N(Z_i q)^2 / k_B T \right] c(1-c)Za^2v_0 \\ &\quad \times \exp(\Delta S/k_B) \exp(-E_m/k_B T) \\ &= (\sigma_0/T) \exp(-E/k_B T). \end{aligned} \quad (11.3)$$

or

$$\sigma_{\text{ion}} = \gamma N(Z_i q)^2 c(1-c) Z a^2 \gamma_0 / k_B T \times \exp(\Delta S / k_B) \exp(-E_m / k_B T) \quad (11.4)$$

This expression shows that σ_{ion} is nonzero only when the product $c(1-c)$ is nonzero. Since all normal sites are fully occupied ($c = 1$) and all interstitial sites are empty ($c = 0$) in a perfect classical crystal, this is expected to lead to highly insulating characteristics. The classical theory of ionic conduction in solids is thus described in terms of the creation and motion of atomic defects, notably vacancies and interstitials.

Three mechanisms for ionic defect formation in oxides should be considered. These are (1) thermally induced intrinsic ionic disorder (such as Schottky and Frenkel defect pairs), (2) redox-induced defects, and (3) impurity-induced defects. The first two categories of defects are predicted from statistical thermodynamics [11.6], and the latter form to satisfy electroneutrality. Examples of typical defect reactions in the three categories, representative of an ionically bonded binary metal oxide, are given in Table 11.1, in which the $K_i(T)$ s represent the respective equilibrium constant and $a_{\text{N}_2\text{O}_3}$ the activity of the dopant oxide N_2O_3 added to the host oxide MO_2 . Schottky and Frenkel disorder (1, 2) leave the stoichiometric balance intact. Reduction–oxidation behavior, as represented by (3), results in an imbalance in the ideal cation-to-anion ratio and thus leads to *nonstoichiometry*. Note that equilibration with the gas phase, by the exchange of oxygen between the crystal lattice and the gas phase, generally results in the simultaneous generation of both ionic and electronic carriers. For completeness, the equilibrium between electrons and holes is given in (4).

Altrivalent impurities [for example N^{3+} substituted for the host cation M^{4+} – see (5)] also contribute to the generation of ionic carriers, commonly more than intrinsic levels do. This follows from the considerably reduced ionization energies required to dissociate impurity-defect pairs as compared to intrinsic defect generation. For example, E_A might correspond to the energy required to dissociate an acceptor–anion vacancy

pair or E_D to the energy needed to dissociate a donor–anion interstitial pair. Such dissociative effects have been extensively reported in both halide and oxide literature [11.7]. A more detailed discussion is provided below in the context of achieving high oxygen ion conductivity in solid oxide electrolytes.

The oxygen ion conductivity σ_i is given by the sum of the oxygen vacancy and interstitial partial conductivities. In all oxygen ion electrolytes of interest, the interstitial does not appear to make significant contributions to the ionic conductivity, and so it is the product of the oxygen vacancy concentration $[\text{V}_\text{O}^{\bullet\bullet}]$, the charge $2q$, and the mobility (μ_v):

$$\sigma_i \approx [\text{V}_\text{O}^{\bullet\bullet}] 2q\mu_v \quad (11.5)$$

Optimized levels of σ_i obviously require a combination of high charge carrier density and mobility.

Classically, high charge carrier densities have been induced in solids by substituting lower valent cations for the host cations [11.2]. Implicit in the requirement for high carrier densities are:

1. High solid solubility of the substituent with the lower valency,
2. Low association energies between the oxygen vacancy and dopant,
3. No long-range ordering of defects.

Additives which induce minimal strain tend to exhibit higher levels of solubility. The fluorite structure is the most well-known of these structures, with stabilized zirconia the best-known example. In this case, Y^{3+} substitutes for approximately 10% of Zr in $\text{Zr}_{1-x}\text{Y}_x\text{O}_{2-x/2}$, leading to $\sigma_i \approx 10^{-1} \text{ S/cm}$ at 1000°C and an activation energy of $\approx 1 \text{ eV}$. Other examples include CeO_2 [11.8], other fluorite-related structures such as the pyrochlores $\text{A}_2\text{B}_2\text{O}_7$ [11.9], and perovskites such as $\text{La}_{1-x}\text{Sr}_x\text{Ga}_{1-y}\text{Mg}_y\text{O}_{3-\delta}$ (LSGM) [11.10].

Since the dopant and vacancy are of opposite charge (for example, Y_{Zr}' and $\text{V}_\text{O}^{\bullet\bullet}$), they tend to associate. With cations being much less mobile than oxygen ions, this serves to trap the charge carrier. It is of interest to examine how the concentration of “free” mobile carriers

Table 11.1 Typical defect reactions

Defect reactions	Mass action relations	
$\text{MO} \rightleftharpoons \text{V}_\text{M}'' + \text{V}_\text{O}^{\bullet\bullet}$	$[\text{V}_\text{M}''][\text{V}_\text{O}^{\bullet\bullet}] = K_S(T)$	(1)
$\text{O}_\text{O} \rightleftharpoons \text{V}_\text{O}^{\bullet\bullet} + \text{O}_\text{i}'$	$[\text{V}_\text{O}^{\bullet\bullet}][\text{O}_\text{i}'] = K_F(T)$	(2)
$\text{O}_\text{O} \rightleftharpoons \text{V}_\text{O}^{\bullet\bullet} + 2\text{e}' + 1/2\text{O}_2$	$[\text{V}_\text{O}^{\bullet\bullet}]n^2 = K_R(T)P_{\text{O}_2}^{-1/2}$	(3)
$0 \rightleftharpoons \text{e}' + \text{h}^\bullet$	$np = K_e(T)$	(4)
$\text{N}_2\text{O}_3(\text{MO}_2) \rightleftharpoons 2\text{N}_\text{M}' + 3\text{O}_\text{O} + \text{V}_\text{O}^{\bullet\bullet}$	$[\text{N}_\text{M}']^2 \cdot [\text{V}_\text{O}^{\bullet\bullet}] / a_{\text{N}_2\text{O}_3} = K_N(T)$	(5)

depends on the dopant concentration and the association energy. Consider the neutrality relation representing vacancy compensation of acceptor impurities by

$$N_V = \beta N_I, \quad (11.6)$$

where N_V and N_I are the vacancy and impurity densities while β reflects the relative charges of the two species and normally takes on values of 1 (for A_M'') and $\frac{1}{2}$ (for A_M'). The association reaction is given by

where x and y are the relative charges of the impurity and vacancy, respectively. The corresponding mass action relation is then

$$N_I N_V / N_{\text{Dim}} = K_A^\circ \exp(-\Delta H_A / kT) \quad (11.8)$$

where N_{Dim} is the concentration of dimers and N_I and N_V are the corresponding defects remaining outside the complexes. It is straightforward to show that for weak dissociation (low temperatures or high association energies) one obtains the following solutions:

$$\beta = 1: \quad N_V = \left(N_I K_A^\circ\right)^{\frac{1}{2}} \exp(-\Delta H_A / 2kT), \quad (11.9)$$

$$\beta < 1: \quad N_V = \left(\frac{1-\beta}{\beta}\right) K_A^\circ \exp(-\Delta H_A / kT). \quad (11.10)$$

The solution for condition $\beta=1$ is the more familiar one. As in semiconductor physics [11.11], the number of free electrons or holes is proportional to the square root of the dopant density at reduced temperature, and it exhibits an Arrhenius dependence with activation energy that is

equal to one half of the association or ionization energy. The solution for condition $\beta < 1$ is more unusual. Here one predicts that N_V is independent of dopant density! Also, the activation energy is predicted to be equal to the association energy.

At sufficiently high temperatures or low association energies, essentially all of the dimers are dissociated and

$$N_V = \beta N_I = \beta N_I (\text{total}). \quad (11.11)$$

In general, therefore, two energies contribute to ionic conduction: a defect energy, E_D (which may either be related to the Frenkel or Schottky formation energy, or to a dissociation energy), and a migration energy E_m . The value of E in (11.3) therefore takes on different values in three characteristic temperature regimes. These include:

1. $E = E_m + E_A/2$: extrinsic associated regime at low T ,
2. $E = E_m$: extrinsic fully dissociated regime at intermediate T ,
3. $E = E_m + E_F/2$: intrinsic defect regime at elevated T (for instance, for Frenkel equilibrium).

For optimized ionic conduction to exist, two criteria must be satisfied simultaneously. First the term c in (11.3) must approach $1/2$. This corresponds to nearly all of the ions on a given sublattice being mobile. Second, the crystal structure must be arranged so as to enable easy motion of ions from one equivalent site to the next. This is reflected in exceptionally low values for the migration energy E_m . In the next section we discuss the conditions under which these criteria are satisfied.

11.2 Fast Ion Conduction

A number of routes leading to exceptionally high ion carrier densities in solids have been identified over the last few decades. These are subdivided into two major categories below (structurally disordered solids and highly defective solids). An important new development in recent years is the focus on the role of interfaces in creating ionic disorder localized in the vicinity of the boundaries. For nanosized structures, these disordered regimes may represent a large fraction of the overall volume of the material. Whatever the source of the enhanced ionic conductivity, such solids are commonly designated as *fast ion conductors* (FIC).

11.2.1 Structurally Disordered Crystalline Solids

In contrast to the idealized picture of crystal structures, many solids exist in which a sublattice of sites is only partially occupied. Strook [11.12, 13] already came to this conclusion in the 1930s in relation to the Ag sublattice in the high-temperature form (α -phase) of AgI. More recent neutron diffraction studies [11.14] differ with regard to the number of equivalent Ag sites. The special feature of partial occupancy of sites is nevertheless sustained.

Fig. 11.2 The temperature dependences of representative FICs, including cation and anion conductors, crystalline and amorphous conductors, and inorganic and organic conductors. After [11.3]

Other notable systems characterized by sublattice disorder include Nasicon ($\text{Na}_3\text{Zr}_2\text{PSi}_2\text{O}_{12}$), sodium beta alumina ($1.2 \text{ Na}_2\text{O} - 0.11 \text{ Al}_2\text{O}_3$) and LiAlSiO_4 ,

Fig. 11.3 Log ionic conductivity versus mole fraction Zr in $\text{Gd}_2(\text{Zr}_x\text{Ti}_{1-x})_2\text{O}_7$ at a series of temperatures. After [11.16]

which exhibit fast ion transport in three, two and one dimensions, respectively. Hundreds of other structurally disordered conductors may be found listed in review articles on the subject [11.2, 15]. Figure 11.2 illustrates the $\log \sigma - 1/T$ relations for representative FICs, while Table 11.2 summarizes data on representative materials in tabular form.

Similarities between FICs and liquid electrolytes are often noted; the most important of these is that the disordered sublattice in the solid resembles the disordered nature of ions in a liquid. For this reason one often hears the term *lattice melting* used to describe phase transitions in solids which relate to the conversion of a conventional ionic conductor to a FIC (such as β to α transition in AgI at approximately 150°C). Nevertheless, most investigators now believe that transport in FICs occurs via correlated jumps between well-defined sites rather than the liquid-like motion characteristic of aqueous or molten salt electrolytes.

The major structural characteristics of FICs include: (a) a highly ordered, immobile or framework sublattice providing continuous open channels for ion transport, and (b) a mobile carrier sublattice which supports a random distribution of carriers over an excess number of equipotential sites. FICs exhibit framework sublattices that minimize strain, electrostatic and polarization contributions to the migration energy while offering high carrier concentrations within the mobile carrier sublattice. Given the high concentration of carriers, correlation effects between carriers must be taken into account. Calculations by Wang et al. [11.17], for example, have demonstrated that cooperative motions of ions can lead to significantly lower calculated migration energies than those based on consideration of isolated jumps alone. Although no precise criterion now exists for categorizing FICs, they normally exhibit unusually high ionic conductivities ($\sigma > 10^{-2} \text{ S/cm}$), well below their melting points, and generally low activation energies (commonly $E \approx 0.05 - 0.5 \text{ eV}$, but they can be as high as $\approx 1.0 \text{ eV}$).

Few intrinsically disordered oxygen ion conducting FICs are known. The pyrochlores, with general formula $\text{A}_2^{3+}\text{B}_2^{4+}\text{O}_7$, represent a particularly interesting system, given that the degree of disorder can be varied almost continuously from low to high values within select solid-solution systems. The pyrochlore crystal structure is a superstructure of the defect fluorite lattice with twice the lattice parameter and one out of eight oxygens missing. This can be viewed as resulting from a need to maintain charge neutrality after substituting trivalent ions for 50% of the quadrivalent ions in the fluorite structure, as in $\text{Gd}_2\text{Zr}_2\text{O}_7$. Although

Table 11.2 Representative solid electrolytes and mixed conductors: mobile ions, electrical properties and applications

Material	Mobile ion	Properties	Remarks and applications
Zr _{0.85} Y _{0.15} O _{2-x} [11.20]	O ²⁻	$\sigma_{O^{2-}}$ (1000 °C) = 0.12 S/cm $E = 0.8$ eV	Material of choice in auto exhaust sensors; prime solid electrolyte candidate for SOFCs
Ce _{0.95} Y _{0.05} O _{2-x} [11.21]	O ²⁻	$\sigma_{O^{2-}}$ (1000 °C) = 0.15 S/cm $E = 0.76$ eV	Semiconducting at low PO ₂ ; prime candidate solid electrolyte for intermediate temperature SOFCs
Ce _{0.1} Gd _{0.9} O _{2-x} [11.22]	O ²⁻	$\sigma_{O^{2-}}$ (800 °C) = 0.10 S/cm $E = 0.56$ eV	
La _{0.8} Sr _{0.2} Ga _{0.8} Mg _{0.2} O _{3-x} [11.23]	O ²⁻	$\sigma_{O^{2-}}$ (750 °C) = 0.35 S/cm $E = 0.55$ eV	Readily converts to mixed conductor by addition of transition metals; candidate solid electrolyte for intermediate temperature SOFCs
Gd _{1.8} Ca _{1.2} Ti ₂ O _{7-x} [11.24]	O ²⁻	$\sigma_{O^{2-}}$ (1000 °C) = 0.05 S/cm $E = 0.67$ eV	The related pyrochlore, Gd ₂ Zr ₂ O ₇ , is an intrinsic FIC
Bi ₂ V _{0.9} Cu _{0.1} O _{5.5-x} [11.25]	O ²⁻	$\sigma_{O^{2-}}$ (700 °C) = 0.15 S/cm $E = 0.47$ eV	Mixed ionic–electronic conductor, $t_{O^{2-}} \approx 0.9$ at 900 K; of interest as a permeation membrane
La _{0.8} Sr _{0.2} MnO _{3+x} [11.26]	O ²⁻	$\sigma_{O^{2-}}$ (1000 °C) $\approx 3 \times 10^{-7}$ S/cm $E = 2.81$ eV	This material is largely an electronic conductor with σ_e (1000 °C) ≈ 100 S/cm; prime candidate as a cathode in SOFC .
BaCe _{0.85} Yb _{0.15} O _{3-x} [11.27]	H ⁺	σ_{H^+} (300 °C) = 7×10^{-4} S/cm $E = 0.54$ eV	Of interest in SOFC based on protonic conduction
Nafion [11.28]	H ⁺	σ_{H^+} (75 °C) $\approx 10^{-2}$ S/cm (at 20% relative humidity)	Organic; prime candidate for low-temperature solid state fuel cell based on protonic conduction
α – AgI [11.29]	Ag ⁺	σ_{Ag^+} (200 °C) = 1.6 S/cm $E = 0.1$ eV	Phase transition at 146 °C; first recognized fast ion conductor
RbAg ₄ I ₅ [11.29]	Ag ⁺	σ_{Ag^+} (30 °C) = 0.3 S/cm $E = 0.09$ eV	One of the most conductive ionic conductors at room temperature
α – CuI [11.30]	Cu ⁺	σ_{Cu^+} (450 °C) = 10^{-1} S/cm $E = 0.15$ eV	Phase transition at 407 °C
Na β -alumina [11.31]	Na ⁺	σ_{Na^+} (300 °C) = 0.13 S/cm $E \approx 0.3$ eV	Stoichiometry varies between Al ₂ O ₃ /Na ₂ O = 5.3–8.5
60Li ₂ S – 40SiS ₂ [11.32]	Li ⁺	σ_{Li^+} (25 °C) = 5×10^{-4} S/cm $E = 0.25$ eV	Amorphous
poly(vinylidene fluoride) (PVdF) – propylene carbonate (PC) – Li salt (LiX = LiSO ₃ CF ₃ LiPF ₆ or LiN(SO ₂ CF ₃) ₂) [11.33]	Li ⁺	σ_{Li^+} (20 °C) $\approx 10^{-3}$ S/cm	Organic conductor; of interest for lithium batteries
β -PbF ₂ [11.34]	F ⁻	σ_{F^-} (100 °C) = 10^{-4} S/cm $E = 0.48$ eV	Basis of a variety of gas sensors

oxygen vacancies occur at random throughout the anion sublattice in an ideal defect fluorite (such as **YSZ**), they are ordered onto particular sites in the pyrochlore structure. Thus, one properly views these as empty interstitial oxygen sites rather than oxygen vacancies. As a consequence, nearly ideal pyrochlore oxides, such as Gd₂Ti₂O₇, are ionic insulators [11.18]. Figure 11.3 illustrates the large increases in ionic conductivity induced

by systematically substituting zirconium for titanium. *Moon and Tuller* [11.16] explain this on the basis of increased A and B cation antisite disorder as the radius of the B ion approaches that of the A ion. Thus, as the cation environments of the oxygen ions becoming more homogeneous, exchange between regular and interstitial sites also becomes more favorable, leading to increased Frenkel disorder. This interpretation has been

confirmed by neutron diffraction studies on a closely related system [11.19].

Other important intrinsically disordered oxygen ion conductors are based on Bi_2O_3 . At 730°C [11.35], the low-temperature semiconducting modification transforms to the δ phase, which is accompanied by an oxide-ion conductivity jump of nearly three orders of magnitude. This is tied to the highly disordered fluorite-type structure, where a quarter of the oxygen sites are intrinsically empty, and to the high polarizability of the bismuth cation. *Takahashi* and *Iwahara* [11.36] succeeded in stabilizing the high-temperature δ phase to well below the transition temperature by doping with various oxides, including rare-earth oxides such as Y_2O_3 . High oxide ion conductivity was also discovered above 570°C in the Aurivillius-type γ phase of $\text{Bi}_4\text{V}_2\text{O}_{11}$ [11.37, 38], where one quarter of the oxygen sites coordinating V^{5+} are empty. Partial substitution of vanadium by lower valence cations, such as copper, nickel or cobalt, led to a new family of so-called BIMEVOX compounds [11.39], with a remarkably high oxygen ion conductivity at moderate temperatures. The copper-substituted compound has an oxide ion conductivity above 200°C which is ≈ 2 orders of magnitude higher than other oxide ion conductors. The bismuth-based electrolytes unfortunately suffer from instability under reducing conditions, which is a limitation for some applications, such as in the solid oxide fuel cells discussed below.

11.2.2 Amorphous Solids

One of the oft-mentioned criteria for FIC in solids (see before) is the existence of a highly ordered framework which provides channels for the ready motion of ions in the complementary, disordered sublattice. Reports of FIC in inorganic glasses [11.40] raised serious doubts concerning the relevance of this feature. The amorphous state, viewed as being liquid-like, is known to lack long-range order, with short-range order typically extending to, at most, a few atom spacings. Although highly oriented channels may be helpful in FIC, they are not essential, as demonstrated by the existence of FIC in glasses.

Fast ionic conductivity is observed in many glasses containing smaller cations with mole fractions greater than about 0.20, such as silver, copper, lithium and sodium [11.41, 42]. These glasses typically contain one or more network formers (such as SiO_2 , B_2O_3 , P_2O_5 or GeS_2), network modifiers (such as Ag_2O , Li_2O , Cu_2O or Ag_2S), and dopant compounds, largely halides (such as

AgI , CuI and LiCl). The network structure and therefore its physical and chemical properties can be substantially modified by addition of the modifier. Dopant salts, on the other hand, do not strongly interact with the network, but *dissolve* into the interstices of the glass structure. A number of phenomenological trends have been noted including: ion conduction increases (1) in the order K , Na , Li , Ag , (2) with increasing modifier concentration, (3) with halide additions in the order Cl , Br , I , (4) in sulfide versus oxide glasses, and (5) in correlation with decreasing density and glass transition temperature.

Some authors speculate that ionic transport in glasses is enhanced upon addition of the halide anions by lowering the association energy between the mobile charge carriers and the network and thereby increasing the free carrier density [11.43]. An alternate model attributes the increased conductivity to major changes induced in the glass structure by the additives, as reflected in changes in glass transition temperature T_g and the density ρ . In this latter model, a large fraction of the carriers are already assumed to be unassociated and free to move, but with increased ionic mobility driven by structural changes. Here [11.44–47], the predominant influence of the halide addition is believed to impact the strain component of the migration energy.

Another important class of amorphous fast ion conductors is those based on organic or polymer electrolytes, which (analogous to the inorganic systems) are composed of a backbone polymer and a salt complex in which the counter-ion is covalently bound to the backbone. A classic example is the one based on polypropylene oxide $(\text{CH}_2\text{CH}(\text{CH}_3)\text{O})_n$ (PPO) complexed with LiCF_3SO_3 to form $\text{PPO}_n \cdot \text{LiCF}_3\text{SO}_3$. Upon forming the complex, the Li ion conductivity increases by as much as a factor of $\approx 10^5$ [11.48]. In contrast to the inorganic glasses, which exhibit an Arrhenius temperature dependence, however, these polymers follow a curved dependence best expressed by

$$\sigma = \sigma_0 \exp\left(-\frac{B}{T - T_0}\right), \quad (11.12)$$

where T_0 is the glass transition temperature. This suggests a coupling between transport and network relaxation, a situation more closely coupled to transport in a liquid than in a solid, albeit a highly viscous liquid. Polymer electrolytes are now materials of choice for Li batteries and proton-based solid electrolytes given their attractive mechanical properties (ability to relax elastically upon stresses induced by volume changes related to charge/discharge of adjacent electrodes) and ease of processing [11.49].

11.2.3 Heavily Doped Defective Solids

Anomalously high concentrations of ionic carriers may also be induced in intrinsically insulating solids. In the following we briefly discuss two approaches for generating such *highly defective solids*.

We already know that ionic defect densities may be greatly enhanced above intrinsic levels by doping with altermultivalent impurities. However, the solubility limit of such impurities is often limited to only tens or hundreds of ppm. This corresponds to roughly 10^{17} – 10^{18} defects/cm³, a value 10^3 – 10^4 times smaller than in typical FICs. Compounds do exist, however, in which the solubility limit is extensive, reaching the 10–20% level even at reduced temperatures. Perhaps the most familiar example of such a system is stabilized zirconia, which due to its wide solid solubility with cations of lower valency such as Ca²⁺ and Y³⁺, exhibits exceptionally high oxygen ion conductivity ($\sigma \approx 10^{-1}$ S/cm) at temperatures approaching 1000 °C.

As discussed above, high carrier densities must be coupled with high ion mobilities in order to attain high magnitudes of ionic conduction. The cubic fluorite structure, exhibited by stabilized zirconia (ZrO₂) and ceria (CeO₂), for example, supports high oxygen ion mobility due to the low four-fold coordination of cations around the oxygens, coupled with the interconnected nature of the face-shared polyhedra which surround the oxygen sites. Migration energies as low as ≈ 0.6 eV are reported for oxygen vacancy motion in ceria-based solid solutions [11.50]. High fluorine ion mobility is also observed in fluorite CaF₂ and related crystal systems.

More recently Ishihara demonstrated that very high oxygen conductivity can be achieved in the perovskite LaGaO₃ by acceptor doping on both the La and Ga sites [11.51]. The solid solution (La_{1-x}Sr_x)(Ga_{1-y}Mg_y)O₃ exhibits ionic conductivity levels above that of ZrO₂ and CeO₂, for example 3×10^{-1} S/cm at 850 °C. Perovskites also support some of the highest proton conductivities at elevated temperatures. The most popular of these are ABO₃-type compounds with A = Ba, Sr, and B = Ce or Zr. Upon acceptor doping, as in SrCe_{0.95}Yb_{0.05}O₃, oxygen vacancies are generated as in the gallate above. However, in the presence of moisture, water is adsorbed and protons are generated [11.52]:

Given the high proton mobility, this is sufficient to induce large proton conductivity. Perovskite-related structures with the general formula A₃B'B''O₉ also

exhibit high protonic conductivity [11.53]. Atomistic calculations simulating proton diffusion in numerous perovskite-type oxides are reported by the group of Catlow [11.54].

Ionic conductivities do not generally increase linearly with foreign atom additions. At the levels of defects being discussed here, defect–defect interactions become important, generally leading to defect ordering. This results in a maximum in ionic conductivity at some level of doping that depends on the particular system being investigated. Nowick and coworkers [11.55, 56] have demonstrated, in a series of studies, that the deviations from ideality are caused initially by composition-dependent activation energies rather than pre-exponentials (11.9), a feature also observed in a number of FIC glasses.

The formation of ionic defects that accompany excursions in composition away from stoichiometry due to redox reactions (Table 11.1, reaction 3) may also be large. CeO₂, for example, may be readily reduced to CeO_{1.8} at 1000 °C [11.57], resulting in oxygen vacancy concentrations of 5×10^{21} cm⁻³ ($c = 0.9$). It should be noted, however, that comparable concentrations of electrons are also formed during such stoichiometry excursions.

11.2.4 Interfacial Ionic Conduction and Nanostructural Effects

Interfaces can significantly modify the ionic conductivities of polycrystalline or composite materials and thin films. Modified levels of ionic conductivity near interfaces may result from space-charge regions formed near interfaces to compensate for charged defects and impurities segregated to surfaces, grain and phase boundaries. Grain boundaries, for example, serve as source and sink for impurities and point defects and thus often take on a net negative or positive charge relative to the grains. To maintain overall charge neutrality, a space charge of opposite charge forms in the grains adjacent to the grain boundaries with a width related to the Debye length L_D given by

$$L_D = (\epsilon_r \epsilon_0 k / T q^2 n_b)^{1/2} \quad (11.14)$$

in which n_b is the majority charge carrier concentration within the grain, $\epsilon_r \epsilon_0$ the dielectric constant, k_B the Boltzmann constant, T the temperature and q is the electron charge. Depending on the sign of the charge at the interface, a depletion or accumulation of mobile ions in the vicinity of the boundary will form. Liang provided

Fig. 11.4 Parallel ionic conductivity of $\text{CaF}_2/\text{BaF}_2$ nanometer-scale, artificially modulated heterolayers, with various periods and interfacial densities in the 430 to 16 nm range. After [11.59]

one of the first demonstrations of enhancement in the $\text{LiI} : \text{Al}_2\text{O}_3$ system [11.58].

The defect concentration profile in the space-charge region can be expressed as [11.60]

$$c_i/c_i^\infty = \exp \left[-q_i(\phi - \phi^\infty)/k_B T \right]. \quad (11.15)$$

The bulk concentration (c_i^∞) is a function of temperature, chemical potential and doping. The local concentration in the space-charge region (c_i) depends

on the difference between the bulk and the local electrical potential (ϕ^∞ and ϕ). For positive values of ϕ , the concentrations of all negative defects are increased by the exponential factor, while those of the positive defects are decreased by the same factor and vice versa for negative values.

Films and/or polycrystalline materials with very small lateral dimensions can be expected to exhibit particularly strong space-charge effects on ionic conduction. This follows from the fact that the space-charge width approaches the dimensions of the film or grain. In this case, the space-charge regions overlap, and the defect densities no longer reach bulk values, even at the center of the particles [11.60]. In the limit of very small grains, local charge neutrality is not satisfied anywhere, and a full depletion (or accumulation) of charge carriers can occur with major consequences for ionic and electronic conductivity. Strong nanoscale effects on ionic and mixed ionic conductivity have been demonstrated for artificially modulated heterolayers of the solid ionic conductors $\text{CaF}_2/\text{BaF}_2$ [11.59] and nanocrystalline CeO_2 [11.61]. Figure 11.4 illustrates the orders of magnitude increase in fluorine ion conductivity possible with space-charge accumulation of mobile carriers in nanoscale $\text{CaF}_2/\text{BaF}_2$ multilayers.

11.3 Mixed Ionic–Electronic Conduction

11.3.1 Defect Equilibria

Deviations from stoichiometry in the direction of oxygen excess (MO_{1+x}) or deficiency (MO_{1-x}) form defect states that act identically in every way to impurity-related acceptor or donor states, respectively. In general, the electrical behavior of solids depends on defects formed in response to both impurities and deviations from stoichiometry. At or near stoichiometry, impurities predominate, while under strongly reducing or oxidizing conditions, defects associated with deviations from stoichiometry often take control. To characterize the electrical response of a metal oxide to temperature and atmosphere excursions, a series of simultaneous reactions of the form represented by (Table 11.1, reactions

1–5) must be considered. Furthermore, a representative electroneutrality equation for the case considered in Table 11.1 would be:

$$2[\text{O}_i''] + [\text{N}_M'] + n = 2[\text{V}_\text{O}^{\bullet\bullet}] + p. \quad (11.16)$$

Note that: (1) intrinsic Frenkel disorder is assumed to predominate, so that (Table 11.1, reaction 1) may be ignored in subsequent discussions; (2) aN_2O_3 is often assumed to be sufficiently low that all of N goes into solid solution.

A piecewise solution to such problems is commonly attempted by sequentially choosing conditions for which only one term on either side of (11.16) need be considered. The region corresponding to mixed ionic conductivity is where the predominant charge carrier is

Fig. 11.5 Defect diagram for acceptor-doped oxide. After [11.62]

an ion. In acceptor-doped material (A' being a generic acceptor), this corresponds to the condition (Region II in Fig. 11.5) for which (11.16) may be simplified to read

$$[N'_M] = [A'_c] = 2[V_O^{\bullet\bullet}]. \quad (11.17)$$

Combining this with (Table 11.1, reaction 3) one obtains

$$n = \left[2K_R(T) / [N'_M] \right]^{1/2} P_{O_2}^{-1/4} \quad (11.18)$$

and from (Table 11.1, reactions 2 and 4),

$$p = K_e(T) \left(2K_R(T) / [N'_M] \right)^{-1/2} P_{O_2}^{1/4}, \quad (11.19)$$

$$[O_i''] = 2[A'_c]^{-1} K_F(T). \quad (11.20)$$

Note that, in this defect regime, the ionic defects are pO_2 -independent while the electronic species exhibit a $pO_2^{\pm 1/4}$ dependence. One obtains predictions for the corresponding dependencies of the partial conductivities of each of these charged species by multiplying carrier concentration by the respective charge and mobility. Experimentally, one normally observes the same pO_2 dependence of the partial conductivity as that predicted for the defect concentration, demonstrating that the mobility is pO_2 -independent. One then uses the predicted pO_2 dependencies of the partial conductivities to deconvolute the ionic and electronic contributions to the electrical conductivity as discussed below.

The three other defect regimes most likely to occur, beginning at low P_{O_2} and moving on to increasing P_{O_2} , are depicted in Fig. 11.5 and include $n = 2[V_O^{\bullet\bullet}]$ (Region I), $p = [N'_M]$ (Region III) and $p = 2[O_i'']$ (Region IV).

In the case where μ_n, μ_p are sufficiently greater than $\mu(V_O^{\bullet\bullet})$, then even in the defect regime where $V_O^{\bullet\bullet}$ is the predominant defect (so that $2[V_O^{\bullet\bullet}] = [N'_M]$), the total conductivity remains electronic. When the carrier mobility inequality is not nearly so pronounced, so that at the pO_2 at which electronic defects are at a minimum ($n = p$), conduction is predominantly ionic. Under these circumstances the oxide acts as a solid electrolyte, and in this regime of temperature and pO_2 , one designates this as the *electrolytic domain*. Aside from the electrolytic domain, the neighboring zones on either side are designated as mixed zones within which both ionic and electronic conductivities are of comparable magnitude.

11.3.2 Electrolytic Domain Boundaries

In applications where solid electrolytes are to be utilized, it is essential to know a priori under which conditions the material is likely to exhibit largely electrolytic characteristics. Expressions for the *electrolytic domain boundaries* can be obtained by first writing down general expressions for the partial conductivities (11.17–11.19):

$$\sigma_i = \sigma_i^\circ \exp(-E_i/kT), \quad (11.21)$$

$$\sigma_p = \sigma_p^\circ P_{O_2}^{+1/4} \exp(-E_p/kT), \quad (11.22)$$

$$\sigma_n = \sigma_n^\circ P_{O_2}^{-1/4} \exp(-E_n/kT). \quad (11.23)$$

One commonly defines the electrolytic domain boundary as that condition of T and pO_2 for which the ionic conductivity drops to 0.5. Under reducing conditions, this pO_2 is designated by P_n and under oxidizing conditions by P_p . Consequently, one equates σ_i and σ_n or σ_i and σ_p to solve for P_n and P_p , respectively. These are given by

$$\ln P_n = \frac{-4(E_n - E_i)}{k} \frac{1}{T} + 4 \ln \left(\frac{\sigma_n^\circ}{\sigma_i^\circ} \right), \quad (11.24)$$

$$\ln P_p = \frac{-4(E_i - E_p)}{k} \frac{1}{T} + 4 \ln \left(\frac{\sigma_i^\circ}{\sigma_p^\circ} \right). \quad (11.25)$$

Note that since the mobilities of vacancies in such oxides have been found to be much greater than those of interstitials [11.16], we ignore the latter's contributions. The domain boundaries for stabilized zirconia are shown plotted in Fig. 11.6 [11.63]. Note that, as commonly observed, the electrolytic domain shrinks with increasing temperature due to the fact that E_n and E_p are typically greater in magnitude than E_i .

11.4 Applications

Fig. 11.6 Domain boundaries of stabilized zirconia as projected onto the $\log P_{O_2} - 1000/T$ plane [11.63]

Fast ionic conducting ceramics and MIECs are finding extensive application in various solid state electrochemical devices. Some of these include fuel cells and electrolyzers [11.2, 64–66], high energy density Li batteries [11.67], electrochromic windows [11.68] and auto exhaust sensors [11.69].

11.4.1 Sensors

The monitoring of our environment has become essential for effective emissions control. Likewise, monitoring of chemical processes in real time enables closer quality control of products. Electrochemical sensors transform a chemical signal into an electrical signal, which is easy to measure, monitor and process [11.70]. Ionic and mixed conducting solids are basic materials for

Fig. 11.7 Schematic of auto exhaust sensor based on the Nernst equation. After [11.64]

this development, because they can be easily miniaturized, for instance in thin film form, and they can often be operated at elevated temperatures or in an aggressive environment. The two major types of electrochemical sensors, potentiometric and amperometric, are summarized below.

Potentiometric Sensors

In a potentiometric gas sensor, the concentration or partial pressure of a species is determined by measuring the emf of a solid electrolyte concentration cell. The most successful commercial sensor is the oxygen sensor [11.64], which uses stabilized zirconia as the solid oxygen ion electrolyte (Fig. 11.7). The emf of the cell, $O_{2,ref}$, Pt / YSZ / Pt, O_2 , can be written according to the Nernst equation:

$$E = t_i(kT/4q) \ln[P(O_2)/P(O_2)_{ref}] . \quad (11.26)$$

$P(O_2)_{ref}$ is the oxygen partial pressure of the reference gas, generally air, and t_i is the ionic transference number. For proper operation, t_i needs to be kept very close to unity. All other terms have their common meanings.

The zirconia auto exhaust sensor monitors the air-to-fuel ratio, which is maintained within close limits for optimum operating efficiency of the three-way exhaust catalyst that serves to reduce the amount of pollutants, including unburned hydrocarbons, CO and NO_x . Such sensors are designed to provide response times on the order of tens of milliseconds. A voltage near to zero corresponds to an oxygen-rich “lean” mixture, and a voltage near to 1 V to an oxygen-poor “rich” mixture. The fuel injector of the engine is controlled via a closed-loop system. The zirconia oxygen sensor sees a wide range of exhaust temperatures, up to values as high as $\approx 900^\circ\text{C}$. Fortunately, the large step in voltage in going from lean to rich conditions can be easily detected at all temperatures. The molecular mechanisms operating at the electrolyte/platinum interface have been examined in detail [11.71].

Another example of a potentiometric sensor is the one reported by Maier et al., of the type [11.72]

This is used to monitor pCO_2 ; it eliminates the need for a gas-tight reference electrode. Here the two-phase reference electrode Na_2ZrO_3, ZrO_2 , which fixes the Na activity on the right side of the cell, is insensitive to

CO₂, while the Na₂CO₃ electrode on the left side can be sensed by the Na⁺-conductor, typically NASICON or β-alumina. Yamazoe and Miura have reviewed the possible different types of potentiometric sensors by using single or multicomponent auxiliary phases [11.73].

Amperometric Sensors

By applying a voltage across an electrolyte, it is possible to electrochemically pump chemical species from one chamber to the other. Amperometric sensors rely on limiting current due to diffusion or interfacial phenomena at the electrode, which are linearly dependent on the partial pressure of the gas constituent [11.74, 75]. These become particularly important in so-called lean burn engines. Here the partial pressure of oxygen does not strongly vary with the air-to-fuel ratio, in contrast to engines operating at or near the stoichiometric air-to-fuel ratio. Under these circumstances, sensors are needed which have a stronger than logarithmic sensitivity to oxygen partial pressure variations. Sensors based on this principle are also being developed to detect other gases including NO_x.

11.4.2 Solid Oxide Fuel Cells (SOFC)

Solid oxide fuel cells (SOFC) provide many advantages over traditional energy conversion systems, including high energy conversion efficiency, fuel flexibility (due to internal reforming), low levels of NO_x and SO_x emissions, versatile plant size and long lifetimes [11.76]. Quiet, vibration-free operation also eliminates noise associated with conventional power-generation systems. However, operation at elevated temperature is necessary given relatively low ionic conductivities and slow

electrode processes at temperatures below 800 °C. Recent progress with thinner electrolytes and advanced electrodes holds promise for reducing operating temperatures by as much as several hundred degrees.

The three major components of the elemental solid oxide fuel cell (SOFC) include the cathode, electrolyte and anode. While the solid electrolyte is selected so that it only conducts ions to ensure a Nernst open circuit potential that is as close to ideal as possible, the electrodes must support the reduction/oxidation reactions that occur at the electrolyte/electrode/gas interfaces. For example, when current is being drawn, the following reaction occurs at the cathode:

This reaction is accelerated if the cathode can provide both electrons, as in a typical current collector, as well as oxygen vacancies. An example of such a mixed conducting cathode is La_{1-x}Sr_xCoO₃ (LSCO), which has an electronic conductivity of > 100 S/cm and an oxygen ion conductivity of > 1 S/cm at temperatures above 800 °C [11.77]. Given its importance to performance, modeling of the electrode processes has also received a great deal of attention recently [11.78, 79]. Unfortunately, while exhibiting highly attractive mixed conducting properties, LSCO is unstable in contact with yttria-stabilized zirconia, the electrolyte of choice.

In an attempt to take advantage of LSCO's attractive features, there is growing interest in marrying this electrode with doped ceria electrolytes, such as Ce_{1-x}M_xO₂:M=Gd or Sm, for operation at reduced temperatures of 550–750 °C, given ceria's higher ionic conductivity (albeit higher mixed ionic electronic conductivity at the anode). Electronic conduction degrades solid electrolyte performance in several ways. Because electronic conduction serves as an alternate path for charged species through the electrolyte, it decreases the power that can be dissipated through the load. Further, the short circuiting factor also serves to allow permeation of gaseous species through the electrolyte, even under open circuit conditions (see the section on membranes below). These primary figures of merit are summarized in the context of a solid oxide fuel cell (SOFC) in Fig. 11.8. E represents the potential induced across the cell under open circuit conditions for a given P_{O_2} gradient, \hat{t}_i is the ionic transference number, E_N is the Nernst potential, R_{INT} , R_C , R_{SE} and R_A are the internal cell, cathode, solid electrolyte and anode resistances, respectively, J_{O_2} is the oxygen permeation flux, and L the thickness across which the P_{O_2} gradient is imposed. All other terms have their normal meanings. Fortunately, the

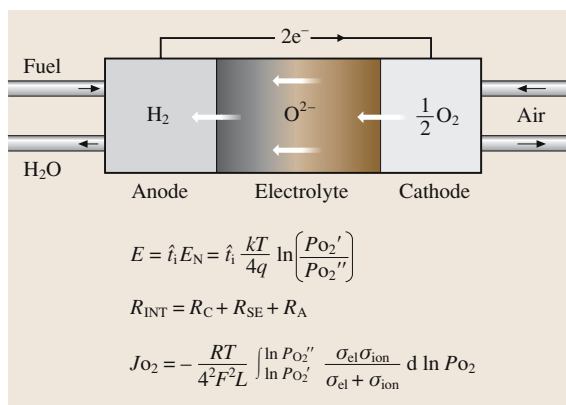

Fig. 11.8 Schematic of a solid oxide fuel cell and the primary figures of merit [11.66]

electronic conductivity in ceria electrolytes drops exponentially with decreasing temperature, and the overall power output exceeds that of zirconia-based systems at reduced temperatures, so it can be used with LSCO and other electrodes incompatible with YSZ.

The system $(\text{La}_{1-x}\text{Sr}_x)(\text{Ga}_{1-y}\text{Mg}_y)\text{O}_3$ (LSGM) was mentioned above as exhibiting one of the highest oxygen ion conductivities ($\approx 3 \times 10^{-1} \text{ S/cm}$ at 850°C) due to high levels of acceptor doping (Sr and Mg) on both the La and Ga sites. As a consequence, it is now being considered as one of several candidates for the electrolyte in solid oxide fuel cells. Experiments have shown that mixed ionic electronic conduction in a fuel cell electrode contributes to reduced overpotentials [11.66]. It has also been recognized that a single-phase *monolithic* fuel cell structure would benefit from the minimization of chemical and thermomechanical degradation [11.80]. Consequently, an electrode based on LSGM would satisfy all requirements. Long et al. proposed to add a transition metal in solution, which would introduce an additional 3d *conducting* band within the wide band-gap of the initially electronically insulating gallate [11.81]. As expected, as the Ni content in the system $\text{La}_{0.9}\text{Sr}_{0.1}\text{Ga}_{1-x}\text{Ni}_x\text{O}_3$ (LSGN) increased, the electronic conductivity increased, finally reaching $\approx 50 \text{ S/cm}$ without decreasing the already high ionic conductivity. Improved electrode performance was indeed observed with the LSGM/LSGN interface [11.82].

11.4.3 Membranes

Oxygen-permeable ceramic membranes are used for the separation of oxygen from air or for industrial-scale oxygen separation in the conversion of natural gas to syngas ($\text{CO} + \text{H}_2$) for example [11.83]. They are made from mixed conducting oxides in which ambipolar diffusion of ionic and electronic charge carriers in an oxygen potential gradient assures a high oxygen permeation flux through the membrane (see Fig. 11.8 for an expression for the permeation current). High oxygen permeation rates were obtained with the system $(\text{La}, \text{Sr})\text{MO}_{3-\delta}$ ($\text{M} = \text{Fe}, \text{Co}, \text{Cr}$) [11.77], but some deterioration over time was noticed. Research continues into this class of materials with regard to long-term ordering of defects, surface exchange kinetics, optimization of oxygen conduction and phase stability under steep oxygen activity gradients. One of the best materials developed to date is the BICUVOX compound, with composition $\text{Bi}_2\text{V}_{0.9}\text{Cu}_{0.1}\text{O}_{5.35}$, which shows a particularly large mixed conductivity that enables high oxygen permeation

rates at moderate temperature, such as 700 K, at high and intermediate oxygen partial pressures [11.38].

Mixed oxide ion and electronic conductivity is also observed in composites of a solid oxide ion electrolyte and a noble metal, if percolating pathways exist for each component. These mixed conducting oxide ceramic-metal composites (cermets), including Y-stabilized ZrO_2 with Pd [11.84], Sm-doped CeO_2 with Pd [11.85], and rare-earth doped Bi_2O_3 with Ag [11.86], have an appreciable oxygen permeation rate at elevated temperature without degradation and are considered attractive for industrial applications, although they are relatively expensive. Recent work by Takamura et al. [11.87] shows promising results based on ceramic/ceramic composites.

11.4.4 Batteries

Power storage requires high energy density batteries. The highest possible energy density is achieved using reactants with high free energies of reaction and low mass, such as lithium or sodium. This also requires that the solid electrolyte remains stable under highly reducing or highly oxidizing conditions. Major advantages of solid electrolytes over liquid electrolytes are the absence of leakage and container problems and, foremost, the possibility of miniaturization; for example using thin solid films.

There is an increasing demand for microbatteries compatible with microelectronics technology, related to the development of laptop computers or portable telephones. This led to the development of high energy density and long life-cycle rechargeable lithium batteries, initially based on metallic lithium anodes. However, systems based on metallic lithium suffered from problems due to metal oxidation and poor rechargeability due to the formation of metallic dendrites. The alternative “rocking chair” concept, proposed in 1980 [11.88], based on two lithium insertion compounds Li_xWO_3 and Li_yTiS_2 , replaced the unstable lithium electrode, but was unable to provide sufficiently high energy densities. Improved rechargeable lithium ion batteries based instead on nongraphitic “hard” carbons as the lithium insertion anodes have since been developed [11.89]. This was followed by the successful association of hard carbon insertion anodes with the high-voltage LiCoO_2 insertion cathode. Due to the relatively high cost of Co, alternative systems based on other cathode materials, such as LiNiO_2 or LiMn_2O_4 , are currently under investigation [11.90]. Polymer (rather than inorganic) electrolytes are used in these applications (see

above). An overview of lithium batteries and polymer electrolytes can be found in books by *Julien* and *Nazri* [11.91] and *Gray* [11.92].

11.4.5 Electrochromic Windows

Electrochromic light transmission modulators – so-called “smart windows” that use solid ionic conductors – may play a significant role in energy-saving by regulating thermal insulation. In such a system, the window is maintained transparent in the visible and reflecting in the IR during the winter, allowing penetration of sunshine but blocking loss of interior heat. On the other hand, the window is rendered partially opaque during hot summer days, reducing the amount of radiation entering the building. The electrochromic elements [11.93], which color or bleach upon insertion/deinsertion of lithium or

hydrogen ions, are sandwiched between two transparent thin-film electrodes and are separated by a solid electrolyte. The transparent electrodes are generally indium tin oxide (ITO). Glass electrolytes appear to be promising choices. Research and development on tungsten trioxide-based electrochromic materials started in the 1970s. Ions fill empty tetrahedral sites in the WO₃ structure [11.94]:

Key requirements include: (1) compatible electrochromic and solid electrolyte thin film materials; (2) the ability to operate near ambient temperature, in the range -40 to $+120^\circ\text{C}$; (3) cycle reversibly many thousands of times a year for a lifetime of 20 years, and; (4) exhibit significant shifts in reflectivity with the degree of insertion/deinsertion.

11.5 Future Trends

A rapidly converging interest in thin film oxides has been developing in the microelectronics and solid state ionics communities. In the solid state ionics arena, the desire to reduce the operating temperature of solid oxide fuel cells (SOFC) has been stimulating a shift in emphasis from bulk to thin film electrolytes. Likewise, the trend in recent years has shifted away from bulk ceramics towards miniaturized smart sensor systems in which the sensor elements are integrated with electronics and various MEMS-based components, including microheaters, valves and membranes. Considering the continued drive towards ever smaller submicron lateral dimensions in MOSFET technology, it is likely that future efforts will be directed towards the construction of micro- and nanoscale ionic devices.

Specifically, one can envision the embedding of miniaturized thin film or SOFC structures as sensors or power sources together with microelectromechanical (MEM) components and other active electronics in the

same silicon wafer. By applying standard Si technology, such as thin film deposition and photolithography, one accesses methods for tailoring electrolyte and electrode geometry (thickness, active electrode area and triple phase boundary length) with exceptionally high dimensional reproducibility, while retaining the ability to scale to larger dimensions. Attention will need to be focused on the special challenges that the marriage between solid state ionics and electronics implies, including semiconductor-compatible processing, rapid temperature excursions, stress-induced property modifications and interfacial stability.

Finally, one will need to consider how the defect and transport properties of thin films may differ from their bulk counterparts, and how the silicon platform provides opportunities to examine such properties in an in situ manner, and thereby identify novel or distinctive properties associated with low-dimensional structures.

12. Bulk Crystal Growth – Methods and Materials

This chapter covers the field of bulk single crystals of materials used in electronics and optoelectronics. These crystals are used in both active and passive modes (to produce devices directly in/on bulk-grown slices of material, or as substrates in epitaxial growth, respectively). Single-crystal material usually provides superior properties to polycrystalline or amorphous equivalents. The various bulk growth techniques are outlined, together with specific critical features, and examples are given of the types of materials (and their current typical sizes) grown by these techniques. Materials covered range from Group IV (Si, Ge, SiGe, diamond, SiC), Group III–V (such as GaAs, InP, nitrides) Group II–IV (including CdTe, ZnSe, [MCT](#)) through to a wide range of oxide/halide/phosphate/borate materials. This chapter is to be treated as a snapshot only; the interested reader is referred to the remainder of the chapters in this Handbook for more specific growth and characterization details on the various materials outlined in this chapter. This chapter also does not cover the more fundamental aspects of the growth of the particular materials covered; for these, the reader is again referred to relevant chapters within the Handbook, or to other sources of information in the general literature.

Despite the widespread progress in several epitaxial growth techniques for producing electronic and optoelectronic device-quality material, various bulk growth methods are still used to produce tens of thousands of tons of such materials each year. These crystals are used in both active and passive modes; in other words, to produce devices directly in/on bulk-grown slices of material, or used as substrates in epitaxial growth, respectively.

This chapter covers the field of bulk single crystals of materials used in electronics and optoelectronics. Single-crystal material usually provides superior properties to polycrystalline or amorphous equivalents. The various bulk growth techniques are outlined, together with specific critical features, and examples are given

of the types of materials grown by these techniques, as well as their current typical sizes. We cover materials ranging from Group IV (Si, Ge, SiGe, diamond, SiC), Group III–V (GaAs, InP, nitrides, among others) and Group II–IV (such as CdTe, ZnSe, [MCT](#)) materials through to various oxides/halides/phosphates/borates. However, this chapter should only be treated as a brief foray into the field. The reader interested in more detail is referred to the chapters following this one (or to other sources of information in the general literature) for more on the growth and characterization of various materials outlined in this chapter. Many of the crystals grown at small sizes, mainly for R&D purposes, particularly in universities, are not discussed; neither, in general, are the organic materials that are being studied in this area.

12.1 History

Several very useful studies on the history of crystal growth in general can be found in the literature [12.1–7]. Many significant contributions were made to the fundamentals of crystal growth during the eighteenth and nineteenth centuries, including the development of thermodynamics, undercooling and supersaturation [12.6, 7]. In terms of crystal growth techniques, it is accepted that the first method applied to produce usable crystals on a large scale was that of flame fusion by Verneuil [12.8].

Before World War II, synthetic crystals (other than ruby) were mainly used in scientific instruments. However, between 1900 and 1940 there were enormous advances in both the theoretical area of this field and in producing samples for scientific study. The diffusion boundary layer was applied by Nernst [12.9], while ideas on the growth of perfect crystals were proposed by Volmer [12.10], Kossel [12.11] and Stranski [12.12].

Table 12.1 Estimated worldwide annual production rates of crystals (as at 1986, [12.1]). Note that some materials are mainly used for non-(electronic/optoelectronic) purposes; for example cubic zirconia and much of the ruby are used in jewelry and watches (items in brackets are small in volume but high in value)

Crystal	Rate (t/yr)	Growth methods
Silicon	4000	Czochralski, float-zone, (VPE)
Metals	4000	Bridgman, Strain anneal
Quartz	800	Hydrothermal
III–V compounds	600	Czochralski, Bridgman (VPE, LPE)
Alkali halides	500	Bridgman, Kyropoulos
Ruby	500	Verneuil
Germanium	400	Czochralski, Bridgman
Garnets	200	Czochralski
Lithium niobate	100	Czochralski
Phosphates	50	Low-temperature solution
Lithium tantalate	20	Czochralski
Cubic zirconia	15	Skull melting
TGS	10	Low-temperature solution
Diamond	10	High-temperature solution
II–VI compounds	5	Vapor, Bridgman

Fig. 12.1 Estimated share of the world production of 20 000 t of bulk crystals (1999). After [12.2], copyright Elsevier Science (used with permission)

Many of the growth techniques now used were also initially developed during this period. The flame fusion of Verneuil [12.8] was followed by hydrothermal growth [12.13, 14], crystal pulling [12.15], Kyropoulos [12.16], Bridgman growth [12.17–20], and vertical gradient freeze [12.21].

During World War II synthetic crystals were used as piezo-electric transducers (in sonar) as resonant devices (in radar) or as infra-red detectors. However, it was the invention of the transistor (announced in 1948) that heralded the modern era of crystal growth for practical purposes rather than for pure scientific interest. Teal and Little developed crystal pulling of Ge in 1950 [12.22] and Dash [12.23] improved this with the ‘necking’ technique to produce dislocation-free material. A key issue at this stage was measuring levels of impurities. The semiconductors used in solid-state devices such as transistors work because they have selected dopants in them. Techniques were developed at this time to improve the purity of materials, such as zone refining [12.24] and float-zone refining [12.25, 26]. Theoretical aspects developed in this period include the role of screw dislocations in growth [12.27] and the generalized theory of Burton et al. [12.28]. Reducing melt inclusions in crystals was discussed by Ivantsov [12.29, 30] in terms of diffusional undercooling, and by Tiller et al. [12.31] in terms of constitutional supercooling. Similar work was carried out in solution growth by Carlson [12.32], who studied flow effects across crystal faces, and Scheel and Elwell [12.33], who derived the maximum stable growth rate and optimized supersaturation to produce inclusion-free crystals. Segregation effects, which are related to mass and heat transfer, were studied by Burton et al. [12.34] for melt growth and by van Erk [12.35] for solution growth,

while the experimental conditions needed to produce striation-free material were established by Rytz and Scheel [12.36]. Forced convection in diffusion-limited growth was recognized as being beneficial for open systems with stirrers [12.37–40], while stirring in sealed containers was accomplished using the accelerated crucible rotation technique [12.41].

In 1986, Brice [12.1] estimated the annual production rates of crystals, and Table 12.1 is a reproduction of that data. Semiconductor materials clearly dominated at that stage, in particular silicon and III–V compounds. Brice also tabulated the uses of the various crystals. Later, Scheel [12.6] gave estimates of

5000 t in 1979, 11 000 t in 1986 (from [12.1]) and approximately 20 000 t in 1999, see Fig. 12.1. By 1999 the balance had shifted somewhat from the earlier estimates, but semiconductors continued to dominate, at $\approx 60\%$. There were roughly equal percentages of scintillator, optical and acousto-optical crystals, at around 10–12%. The remainder were made up of laser and non-linear optical crystals and crystals for jewelry and the watch industries.

A recent book edited by Capper [12.42] gives a comprehensive update on the bulk growth of many of the materials used in the electronic, optical and optoelectronic fields.

12.2 Techniques

12.2.1 Verneuil

This is the fastest growth method and was the first found to be capable of controlling nucleation and thus producing large crystals of high melting point oxide crystals, such as sapphire and ruby. Currently, a large number of high melting point materials have been grown by this technique, including ZrO_2 (2700 °C), SrO (2420 °C) and Y_2O_3 (2420 °C), but the largest use is still Al_2O_3 (often doped to produce ruby, sapphire, and so on). Figure 12.2 shows a schematic of the equipment used. Many different heat sources have been used, such as solar furnaces, glow discharges, plasma torches, arc images and radio-frequency heating, but the original gas flame technique is still the most popular. An oxy-hydrogen flame heats the seed crystal, which is placed on a ceramic pedestal. Powder from a hopper is shaken through the flame and melts, forming a melt surface on the seed. During growth, the seed is lowered, controlling the linear growth rate, while the volume growth rate is governed by the powder feed rate. The balance of these two rates controls the crystal diameter and the crystal is normally rotated slowly. Ruby crystals up to 200 mm in diameter can be grown. Drawbacks of the technique include high dislocation densities and concentration variations.

12.2.2 Czochralski

Czochralski is a fast growth method widely used for both semiconductors and oxide/fluoride materials intended for optical applications. It usually also produces the most homogeneous crystals and those with the fewest flaws. However, it is only really applicable to those materials

that melt congruently or nearly congruently, so that the solid and the melt compositions are the same at equilibrium. A crucible material is normally needed that is compatible with the melt, but the crucible material most commonly used for silicon – silica – dissolves slowly in the melt and this raises certain process issues about

Fig. 12.2 Schematic of Verneuil growth equipment. (After [12.1])

the growth of this material. Capital costs for Czochralski pulling are higher than most other techniques, but it is used when the greatest perfection is required.

The largest use is clearly for silicon, but ≈ 100 materials are grown commercially using this method, while many more are at the research stage. As the diameter of the crystal increases, for example from 200 mm to 300 mm for silicon, controlling dislocations becomes more difficult due to increased radial temperature gradients. Figure 12.3 shows a schematic of Czochralski growth equipment. The basic method is relatively simple: the solid charge is placed in the crucible and heated to a temperature several degrees above the melting point. The seed crystal, rotating slowly, is lowered to contact the melt and the seed then slowly melts. After a short delay (a few minutes), pulling is commenced and new material (with slightly reduced diameter) begins to grow. A long narrow 'neck' region is grown to reduce dislocations, and then the melt temperature is reduced to increase the diameter. When the crystal attains full diameter, growth is maintained until the desired length of crystal has grown, and growth is terminated by sharply increasing the pull rate or increasing the melt temperature so that the diameter reduces to zero.

Constant diameter is maintained by adjusting the power input to the melt. This is done automatically, ei-

ther by directly monitoring the diameter optically (by observing the bright ring around the crystal periphery), or by indirectly measuring the diameter via weighing methods. Crucibles are normally round-based for semi-conductors but should be relatively flat for oxide/halide growth (for ionic materials). Often the depth of the initial melt is the same as or slightly less than the diameter of the crystal.

Hurle [12.43] discusses the effects, in detail, of convection, flows in melts, heat transport, mass transport, solute segregation, use of magnetic fields, systems dynamics and automatic diameter control, morphological stability and defect control. In general, as melt sizes have increased natural convective flows have also increased, leading to turbulence, which causes growth rate fluctuations leading to dopant concentration variations (so-called "striations").

For the growth of III–V compounds, liquid-encapsulated Czochralski (LEC) was pioneered by *Mullin* and coworkers [12.44] for GaAs and GaP. Suppressing the volatility of As and P was crucial to the successful growth of these types of compounds. This technique involves the use of an inert layer of a transparent liquid, usually B_2O_3 , which floats on the melt surface and acts as a liquid seal. Most importantly, the encapsulant should wet both the crucible and crystal so that a thin film adheres to the crystal as growth proceeds. The latter prevents dissociation of the hot crystal. PBN crucibles are often used these days, and either resistance or RF heating is employed. Semi-insulating GaAs is produced in a high-pressure puller (100–200 atm). The main advantage here is that elemental Ga and As can be used as the starting materials. Diameter is often controlled via crystal-weight measurements, rather than by meniscus observation. Pull rates are typically < 1 cm/h. Axial or transverse magnetic fields can again be used to control melt turbulence and dopant segregation.

Precious metal (Pt, Ir) crucibles are used for oxide crystal growth, as high temperatures are used. To prevent the reduction of oxide melts, a partial pressure of oxygen is needed. Normally, the crucible is not rotated or translated and the growth rate is greater than the pulling rate as the melt height decreases. Stable growth rates are obtained for crystal diameters of less than half the crucible diameter. Growth rates are a few mm/h at best, so growth times are normally > 1 week. Large temperature gradients can lead to melt turbulence, which in turn produces a banded structure of solute concentration and varying stoichiometry in the crystals. Controlling convection in these systems is therefore of critical importance.

Fig. 12.3 Schematic of Czochralski growth equipment. (After [12.1])

12.2.3 Kyropoulos

This simple technique is used where a large diameter is more important than the length, as in the cases of windows, prisms, lenses and other optical components, and for scintillator materials. The set-up and method of growth are similar to those of Czochralski (Fig. 12.4), but after the seed is brought into contact with the melt it is not raised much during growth. As in Czochralski, a short necked region is still grown but then the seed removal is stopped and growth proceeds by reducing the input power to the melt. The resulting crystals normally have diameters of $\approx 80 - 90\%$ of the crucible diameter. Although the control systems used for this process are relatively simple, the temperature distribution over the crucible is critical. For alkali halides the crystal density is greater than the melt density, so the melt level decreases with growth, and the desired temperature distribution is one of increasing temperature as the base of the crucible is approached. Average linear growth rates are a few mm/h, corresponding to cooling rates of $< 1^\circ\text{C/h}$. The only other process parameter of concern is the seed rotation rate, which is normally low or zero.

While the method appears to be very attractive economically, there are technical deficiencies. The isothermal surfaces are curved, resulting in high dislocation densities, and the growth interface is composed of different crystal faces, with consequent inhomogeneities in impurities and vacancy concentrations. High levels of impurities result from the majority of the melt (which is not stirred well) being consumed. Despite these drawbacks, many tons of alkali halides are grown for optical applications each year by this technique.

12.2.4 Stepanov

In this technique, a crystal is pulled from a crucible containing a crystal-shaped aperture (Fig. 12.5). Crystals can be pulled vertically upwards, downwards, or even horizontally. Growth rates are below those of the normal Czochralski technique, but dislocation densities can be reasonably low.

12.2.5 Edge-Defined Film Growth

A die with a central capillary is placed on the surface of the melt (Fig. 12.6). Surface tension forces cause the melt to wet the die and be drawn up the capillary. A pointed seed crystal is lowered to contact this melt and then pulled upwards. The melt is cooled slightly to increase the crystal diameter until it reaches the size of

Fig. 12.4a–c Schematic of Kyropoulos growth equipment. (a) The seed crystal contacts the melt, a small amount melts and then cooling is commenced to produce (b) and (c). (After [12.1])

Fig. 12.5 Schematic of Stepanov growth equipment, in which a crystal is pulled through an aperture that defines its shape. (After [12.1])

Fig. 12.6a–c Schematic of edge-defined film growth equipment. (a) The melt wets the die and is drawn up the capillary; (b) the seed is contacted to the melt and pulled up and cooling starts to increase the crystal size; (c) the crystal reaches the size of the die. (After [12.1])

the die. Die can be designed to produce various shapes of crystals, including tubes and sheets. Rapid growth is possible, but crystal quality normally suffers. One product is alumina tape (1 mm thick by several centimeters wide) used as a substrate for the production of high-frequency circuits. In this technique, however, purity can be limited.

12.2.6 Bridgman

In essence, this is a method of producing a crystal from a melt by progressively freezing it from one end to the other (Fig. 12.7). Crystals can be obtained with good dimensional control and the method uses relatively simple technology requiring little supervision. However, as the diameter increases, controlling heat flow becomes progressively more difficult. A wide range of materials have been produced by this technique, including sapphire at a melting point of $\approx 2370^\circ\text{C}$. One major requirement is that neither the melt nor its vapor must attack the crucible material significantly. Dislocation densities can also be limited to $> 10^4 \text{ cm}^{-2}$, and many materials contain low-angle grain boundaries.

Fig. 12.7 Schematic of Bridgman growth equipment. (After [12.1])

Growth rates can be in the range 0.1–30 mm/h. Either the crucible or the furnace can be moved to achieve movement of the freezing isotherm, and both vertical and horizontal orientations are used. If vibration is an issue in a particular growth system, then it is usually preferable to move the furnace rather than the crystal. Crucible materials include silica (for covalently bonded crystals), graphite and some metals (such as Mo for sapphire growth). The crucibles traditionally have tapered tips in order to try to restrict nucleation to one crystal, although seed crystals can also be used. If spurious nucleation occurs it usually forms at the crucible walls, but these can be suppressed by making the growth face concave into the melt. Baffles are often used to separate upper and lower parts of the furnace to ensure thermal isolation. A low radial temperature gradient is needed to reduce dislocation densities. Calculating the temperature distribution is possible [12.45]. The most obvious requirements are a large temperature gradient at the growth interface and low temperature gradients in the radial direction.

Impurity distributions in crystals are, in general, governed by the type of mixing in the melt. In stirred melts – so-called normal freezing – the relevant equation is

$$C_s = k_{\text{eff}} C_0 (1 - x) k_{\text{eff}} - 1,$$

where C_s = concentration in the solid, C_0 = initial concentration, k_{eff} = effective distribution coefficient, and x is the fraction solidified. In unstirred melts, the interface segregation coefficient k^* governs

$$C_s = k^* C_0 (1 - [(1 - k^*)/k] \times \{1 - \exp[-(1 - k^*)k^* f_z / D_L]\}),$$

where f is the growth rate, z the axial distance, and D_L is the diffusion coefficient. For a molten zone of length L , the equation is

$$C_s = C_0 [1 + (k_{\text{eff}} - 1) \exp(-k_{\text{eff}} x)].$$

For materials with a volatile component there are several possible refinements of the basic process, such as sealed ampoules, overpressure and liquid encapsulation (for example using B_2O_3). In sealed-ampoule growth there is normally a lack of control over stirring. The accelerated crucible rotation technique (ACRT) can be used for vertical systems, and this author has developed this refinement for the growth of cadmium mercury telluride up to 20 mm in diameter [12.46]. Faster stable growth rates are possible with ACRT [12.46], as are larger diameter crystals, improved uniformity and better crystallinity.

It is worth noting that the majority of melt-grown crystals are produced by the Bridgman and Czochralski techniques (and their variants). In general, if no suitable crucible can be found, then other methods are required, such as the Verneuil method.

12.2.7 Vertical Gradient Freeze

The vertical gradient freeze (VGF) technique involves the progressive freezing of the lower end of a melt upwards. This freezing process can be controlled by moving the furnace past the melt or, preferable, by moving the temperature gradient in a furnace with several independently controlled zones. Low-temperature gradients are normally obtained, leading to reduced dislocation densities, and the crystal is of a defined shape and size. Difficulties include furnace design, the choice of boat material, and the issue of seeding.

12.2.8 Float Zone

In this technique a molten zone is maintained between two solid rods (Fig. 12.8). By moving the zone relative to the rods, one of them grows, and a single crystal can be grown if a seed is used. Silicon is the

Fig. 12.8 Schematic of float-zone growth equipment. (After [12.1])

only material grown on a large scale by this technique. The only other use for it is in the small-scale growth of very pure crystals, as no crucible contact is involved. For silicon, RF heating is used, with frequencies of 2–3 MHz for diameters > 70 mm. There is a steep temperature gradient that induces flows in the molten zone, and if both the seed and feed rods are rotated then the shape of the solid/liquid interface can be controlled. The molten zone normally moves upwards.

12.2.9 Travelling Heater Method (THM)

This technique was developed for II–VI alloy growth (Te-based) by Triboulet [12.47]. In the technique, a molten zone is made to migrate through homogeneous solid source material. This is normally accomplished by slowly moving the ampoule relative to the heater (Fig. 12.9). The key requirement here is to obtain the appropriate temperature profile, also shown in Fig. 12.9. Matter transport is by convection and diffusion across the solvent zone under the influence of the temperature gradient resulting from the movement. For alloy growth, a steady state can be reached where the solvent dissolves a solid of composition C_0 at the upper growth interface and deposits, at near-equilibrium conditions, a material of the same composition at the lower growth interface. Growth occurs at a constant temperature below the solidus temperature and hence shows all the advantages of low-temperature growth. When tellurium was used as the molten zone there

Fig. 12.9 Schematic of travelling heater method growth equipment. (After [12.1])

was a marked purification effect. Seeding was also found to be possible with the technique, as was growth to a larger diameter than achieved with the other common melt techniques used for these compounds.

Problems with THM include the availability of suitable feed material with the required composition and dimensions, although several different routes have been used to overcome this problem. Natural convection is the dominant mechanism of material transport, which led to the addition of ACRT to the basic THM method for some of the ternary alloys.

Graded composition alloys were also made by producing two bevelled cylinders of binary compounds. These were then used to assess the effects of composition on various electrical and optical properties in the given system. Other modifications to the basic process included the 'cold THM' process, in which the relevant metallic elements were used as the source material. This produced a process that accomplished synthesis, growth and purification at low temperature all in a single run. To avoid the problems resulting from solvent excess in the crystal, 'sublimation THM' was developed, in which an empty space of the same dimension as the molten zone is used. This method was successfully applied to the growth of ZnSe. Repeated runs on the same material were used to improve the purification effect. A drawback of this is repeated handling, which in turn was solved by using the 'multipass THM' technique, which can be thought of as a variety of the classical zone-melting method.

12.2.10 Low-Temperature Solution Growth

Most of the crystals grown by this technique are water soluble. This limits their use to applications in which moisture can be excluded. Growth rates are low (0.1–10 mm/d), as the growth faces are unstable. This is due to the concentration gradient near the growth face, in addition to which the crystal is normally totally immersed in the solution so that latent heat evolved increases the adverse supersaturation gradient (Fig. 12.10).

Water (both light and heavy) is used in $\approx 95\%$ of the cases, and must be highly pure. All equipment must be carefully cleaned and protected from dust and the solutions must be stirred vigorously while being prepared. Both slow cooling and solvent evaporation techniques are used. Large volumes of solution (> 100 l) are needed for very large crystals of, for example, KH_2PO_4 (KDP). These large volumes imply very long thermal time

Fig. 12.10 Schematic of low-temperature solution growth equipment. (After [12.1])

constants, which can be increased by adding thermal insulation, up to a limit. Large time constants make it easy to obtain good temperature control. The growth equipment is normally held in temperature-controlled rooms. Although temperature stability is key, other parameters, such as fluctuations in stirring, can lead to large changes in growth rate too.

Solvent evaporation simplifies the temperature control system and makes it more reliable. However, it is difficult to ensure a constant acceptable rate of loss of solvent. This can be approached by using a water-cooled condensation region. One drawback of this technique is that concentrations of impurities increase as the growth proceeds.

12.2.11 High-Temperature Solution Growth (Flux)

This method is used for those materials that melt incongruently; the solvent (flux) reduces the freezing point below the relevant temperature to produce the desired phase of the compound. Both liquid metals (such as Ga, In, Sn) used in semiconductors and oxides/halides (such as PbO and PbF_2) used for ionic materials are employed as solvents. Often, an excess of one of the components will be used (Ga for GaAs and GaP for instance) or a common ionic material (such as K_2CO_3 for $\text{KTa}_x\text{Nb}_{1-x}\text{O}_3$). Alternatively, the solvents con-

Fig. 12.11 Schematic of hydrothermal growth equipment. (After [12.1])

tain large atoms, such as Pb and Bi, which are too large to enter the lattice of the desired crystal. Mixed solvents, such as alkali metal ions, break the chains that exist in B_2O_3 , SiO_2 and Bi_2O_3 , lowering viscosities and surface tensions. The book by *Elwell and Scheel* [12.5] contains much useful information about this topic.

Slow cooling of high-temperature solutions was used between 1950 and 1970 to produce hundreds of different materials. Small crystals were normally obtained but these were sufficient to obtain useful measurements of magnetic, optical and dielectric properties. Later, seeded growth and stirring using *ACRT* led to much larger crystals. A Czochralski-type pulling technique can also be used in high-temperature solution growth to produce larger crystals.

Diamond is produced at high temperature ($> 1500\text{ K}$) and high pressure ($> 50\text{ kbar}$). Solvents used include Pt, Pd, Mn, Cr and Ta, but better results were obtained with Ni, Co and Fe and their alloys.

12.2.12 Hydrothermal

This is growth from aqueous solution at high temperature and pressure. Most materials grown have low solubilities in pure water, so other materials (called

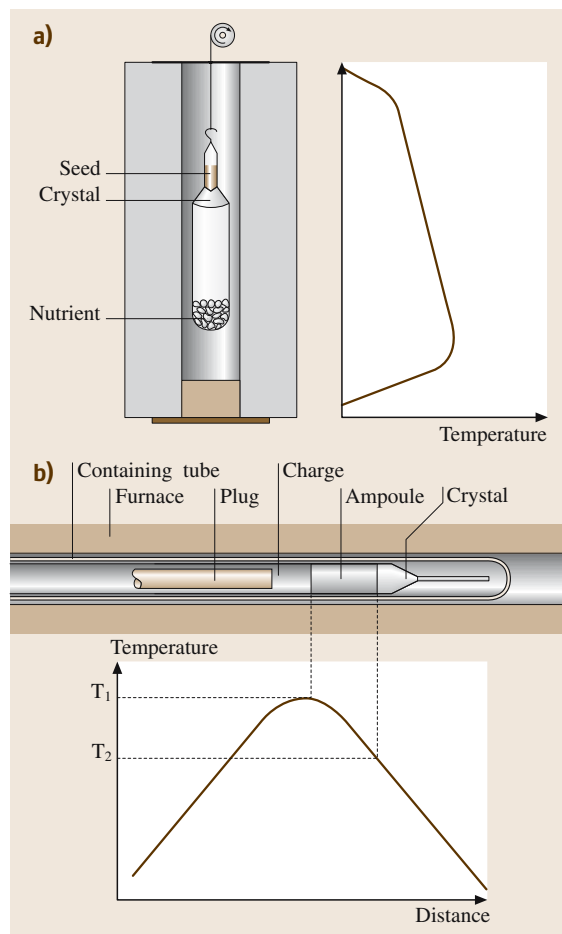

Fig. 12.12a,b Schematic of vapor growth equipment. (a) Seeded growth; (b) Piper-Polich set-up. (After [12.1])

mineralizers, such as $NaOH$ and Na_2CO_3) are added to increase the solubility. Quartz is the only material grown on a significant scale by this method, although ZnO is also produced commercially by this technique.

Natural quartz crystals are used as seeds, as they have lower dislocation densities. Growth proceeds in the temperature gradient transfer mode. Nutrient is held in the lower part of the liquid in an autoclave. This region is held at between 5 and 50°C above the upper portion of the autoclave. Convection carries the hot supersaturated liquid to the cooler upper regions, where deposition occurs on the seed crystals (Fig. 12.11). These autoclaves can be operated at up to 400°C and 2000 atm pressure for approximately 10 years without degradation. Autoclaves can be up to 1 m in diameter and 2.5 m high

for low-pressure growth from Na_2CO_3 solution, while 40-cm-diameter and 8-m-high autoclaves are typical of growth from NaOH .

Resistive heating elements are strapped to the outside of the autoclave and connected to two control systems, allowing independent control of the temperatures in the solution and growth zones. *Brice* [12.1] presents a table that shows some typical hydrothermal growth conditions for a wide range of materials.

The essential problem in the growth of quartz is to produce useful devices with reasonable yields with OH concentration (measured by IR absorption) of < 100 ppm. Several parameters restrict the maximum growth rate to ≈ 0.5 mm/d.

12.3 Materials Grown

This section attempts to summarize the current position regarding the wide range of materials used in electronics and optoelectronics. Again the reader is referred to the following relevant chapters for more in-depth coverage of a particular material. The section is subdivided roughly into Group IV, Group III–V, Group II–VI, oxides, halides, and finally phosphates/borates.

12.3.1 Group IV

Silicon and Germanium

The growth of silicon still dominates the electronics industry in terms of size of activity. *Hurle* [12.43] describes in detail the growth of silicon by the Czochralski method. In essence a polysilicon charge is placed in a high-purity quartz crucible mounted in prebaked graphite supports. Chains or cables are used in the pulling system, rather than rods, to limit the height of modern pullers. Both the crystal and the crucible can be rotated, although the details of this aspect vary from manufacturer to manufacturer and are proprietary. As the growth proceeds, the crucible is raised to maintain the position of the melt surface in the heater.

Silicon has two major advantages from a crystal growth perspective: a high thermal conductivity (which permits the latent heat of solidification to be removed) and a high critical resolved shear stress (which allows high thermal gradients without dislocation generation). These two factors enable high growth rates, leading to economic benefits. Heat is provided by ‘picket fence’-type graphite heaters. Most commercial pullers are highly automated with full computer control. In most cases, diameter control is achieved via monitoring of the

12.2.13 Growth from the Vapor

Vapor growth has some applications, particularly in high melting point materials and in II–VI compounds such as ZnSe and ZnS (Fig. 12.12). High-temperature vapor transport, or sublimation, of SiC has progressed recently and is now able to produce 1–2-inch crystals. Growth proceeds by sublimation of a SiC source at 2000–2500 °C in near-vacuum conditions onto a seed held at ≈ 1000 °C lower than the source. 6H-polytype material oriented at $\langle 0001 \rangle$ is produced. Growth rates are ≈ 2 mm/h. Remaining problems include impurities ($\approx 10^{16} \text{ cm}^{-3}$), voids, high dislocation densities and mixed polymorphism.

‘bright ring’ around the meniscus of the growing crystal. Oxygen is a particular problem and is introduced via erosion of the silica crucible by the melt. Convection moves the oxygen within the melt towards the crystal, where it is incorporated. Slightly reduced pressure over the melt can help to remove oxygen from the melt as silicon monoxide. A similar situation arises with carbon monoxide loss from the melt. Problems with convection have increased as the diameters of silicon crystals have increased over the past several decades. This convection controls the concentrations and distributions of oxygen, carbon and other unwanted impurities.

Although current production of large-diameter material is at the 300 mm level, there have been recent reports of 400 mm-diameter material [12.48]. In this case it was necessary to grow a secondary neck below the Dash dislocation-reducing one, as the thin Dash neck could not hold the weight of the crystal. Crystals of up to 438 kg and 1100 mm in length were reported. A recent report [12.49] shows how codoping Si with B and Ge can obviate the need for this narrow neck region, while maintaining dislocation-free growth.

The highest grade of silicon (the highest purity) is probably still produced by the float-zone method, rather than the Czochralski technique [12.50, 51]. The higher purity (particularly regarding carbon and oxygen) and better microdefect control result in higher solar cell efficiencies in FZ material. Faster growth rates and heating/cooling times together with the absence of crucibles and hot-zone consumables also give FZ material an economic advantage over Czochralski material.

Table 12.2 summarizes the present position on sizes of various crystals, including silicon and germanium.

Table 12.2 Typical sizes (diameters) of a selection of bulk-grown crystals (in mm and/or weight in kg) currently in production and used in R&D

Crystal	Commercial	R&D
Silicon (Cz)	300 (250 kg)	400 (438 kg)
Silicon (FZ)	100	
Germanium	75	200–300
Silicon/Germanium		35 (120 mm long)
SiC	50	100
Diamond	10	10 × 10
GaAs	150 (50 kg)	200
InP	100	150
GaSb	50	75
InSb	75	100
InAs	50	
InGaAs		10
GaN (sublimation)	50	
MCT	20	40
CdZnTe	140 (10 kg)	140 (12 kg)
Bi ₂ Te ₃	12	28
ZnSe (vapor, LEC)	60	
ZnTe	80	
ZnO	50	
HgMnTe	30	
HgZnTe	30	
LiNbO ₃		40
PbZnNbTiO ₃		75
YAG	20	75
LiTaO ₃	100	125
Ruby	200	
BGO		130
La ₃ Ga ₅ SiO ₁₄		100
Quartz	15 – 30 × 150 – 250, (0.5–18 kg)	
CaF ₂	385 (100 kg)	
Alkali halides	500 (550 kg)	1000?
Phosphates	45 × 45 × 86	
TGS	40	

The author does not claim that this list is complete nor is it authoritative, it merely serves to show the range of crystals and sizes currently being grown by bulk growth techniques. The information is taken from a number of recently published conference proceedings [12.52–57] and other sources [12.42, 58–60].

Silicon Carbide

The growth of SiC for semiconductor devices, as opposed to abrasive applications, became successful when substrates could be reproducibly grown up to large sizes [12.61–63]. Currently, substrates up to 50 mm

in diameter are commercially available and 100 mm-diameter substrates have been reported. The current method is that of seeded sublimation growth. A water-cooled quartz reactor enclosure surrounds a graphite crucible, which is heated by means of RF. Crucible sizes are slightly larger than the required crystal size and SiC powder (particle size 20–200 μm) and/or sintered polysilicon is used as the source. A distance of 1–20 mm between the seed and the source is typically used. At the high process temperatures of 1800–2400 °C, volatile species of Si₂C, SiC₂ and Si evaporate from the source and deposit on the seed. The source temperature de-

termines the rate of evaporation, and the temperature difference between the source and the seed determines the diffusion transport rate; together these two temperatures govern the growth rate. The Si:C ratio is a key control parameter for proper growth of the desired material. Sublimation is normally performed in vacuum or inert gas, such as argon. The pressure of this gas also controls the growth rate to an extent. Growth rates can reach up to 0.5–1.0 mm/h, and crystal lengths of up to 20–40 mm are achieved. Doping can be accomplished via nitrogen and aluminium addition for n- and p-type material, respectively.

Polytype control is obtained by carefully choosing the seed orientation, with growth on the (0001)Si face giving 6H material, while 4H material grows on the (0001) face. Both growth temperature and pressure and intentional/unintentional impurities can also affect the polytype obtained. One remaining problem is that of micropipes within the material. These are hollow core defects of 1–10 μm diameter, although their density has been reduced from 1000 to 1 cm^{-2} in the best recent samples. Maintaining good control over the nucleation conditions can reduce micropipe density.

Diamond

High-pressure diamond is produced under conditions where it is thermodynamically more stable than graphite [12.64]. However, very high temperatures and pressures are required for growth, unless catalysts are also employed. Clearly a detailed knowledge of the diamond–graphite pressure–temperature phase diagram is a prerequisite for successful growth. For example, in static compression, 8–20 GPa of pressure and temperatures of 1000–3000 $^{\circ}\text{C}$ are needed. Carbon sources include graphite, amorphous carbon, glassy carbon and C_{60} . Dynamic compression techniques employ pressures of 7–150 GPa. A wide variety of catalysts have been used, ranging from conventional ones, such as transition metals, to carbide-forming elements (including Ti and Zr), to Mg, to oxygen-containing materials (carbonates and hydroxides for instance), to inert elements (such as P, Cu, Zn) to hydrides.

Crystals above 1 mm in size are grown by the temperature gradient method. Growth temperature, temperature gradient, growing time, type of catalyst and impurities all affect the growth. Crystals up to 10 mm in size are commercially available. Growth rates can reach 10 mg/h and are governed by the growth temperature and the temperature gradient. If a high-quality diamond seed is used, crystals free of major defects (such as inclusions, stacking faults and dislocations) can be obtained. Impurities,

mainly from the catalysts used, are still an issue, as is their nonuniform distribution.

12.3.2 Groups III–V

Gallium Arsenide (GaAs)

Mullin [12.44] provides a comprehensive discussion on all aspects of the growth of III–V and II–VI compounds. He starts his treatment with the early work done on purification in Ge and Si, which highlighted the need for both high purity and for single-crystal growth. He notes that *Pfann* [12.65] initiated zone melting, where, in the simplest case, a horizontal molten charge is progressively frozen from one end. Both zone leveling (in which a liquid zone within a solid bar is moved through the bar in one direction and then in the reverse direction, thus producing a uniform distribution of a dopant) and zone melting (in which liquid zones are repeatedly passed through a solid bar to force impurities to segregate to the ends of the bar, and then these are subsequently removed before the bar is used in growth) are used. Horizontal techniques were also used to produce single-crystal material by slight back-melting of a seed crystal, followed by progressive freezing. These various horizontal techniques were subsequently applied to the purification of both elements and compounds in materials from Groups III–V and II–VI.

Table 12.3, taken from [12.44], summarizes the growth techniques that have been used for the various compounds in Groups III–V and II–VI. There is much current debate about the relative advantages and disadvantages of these techniques as applied to compound crystal growth.

GaAs is the most important Group III–V compound. Horizontal growth can be used to produce low temperature gradients at the solid/liquid interface, which reduces stress-induced slip and hence dislocations. This is particularly beneficial for the use of GaAs in laser diodes, where dislocation densities are required to be very low. However, there is a potential problem in using these low temperature gradients – constitutional supercooling – which may result in unstable growth and second-phase inclusions. In addition to this, there is the issue of impurity uptake from the crucible and nucleation of twins, grain boundaries and even polycrystalline growth from the crucible walls. These problems can be minimized by taking care over experimental details, but they still make horizontal growth unattractive where large-area uniformity is required, particularly as scaling up to ever-larger diameters is difficult.

Table 12.3 General applicability of growth techniques to compound semiconductors. The more asterisks, the more appropriate the technique. *P*: potentially applicable; *C*: conventional VGF; *L*: LEC VGF. (From [12.44])

Technique/ Compound	Zone melting, horizontal Bridgman	VGF, vertical Bridgman	Conventional vertical pulling	Liquid encapsulation pulling	Vapor growth
InSb	***	P	***		P
GaSb	***	P	***		P

HgSe		**			P
HgTe		***			P
CdSe	*	**			***
CdTe	***	***			***
ZnSe		**			***
ZnTe		**			***
HgS					***
ZnS					***
CdS					***

Early efforts to produce this material by the vertical Czochralski method failed due to dissociation of the melt. This problem was solved by the LEC technique [12.44]. A layer of boric oxide floats on the melt and the seed crystal is dipped through this to contact the melt (Fig. 12.13). PBN crucibles are normally used and heating can be by resistance or RF means, but commercial systems use graphite heaters. Most semi-insulating GaAs, which is required for integrated circuits, is produced at pressures of 100–200 atm. The advantage of this modification is that elemental As and Ga can be used as the source. Diameter control is normally via crystal weighing. Currently, LEC produces material 150 mm in diameter [12.66] from 28–40 kg melts using 400 mm-diameter PBN crucibles. Also reported were modifications to the basic Czochralski technique to reduce stresses, and hence dislocations, in crystals up to 100–150 mm in diameter. These are

vapor pressure controlled Czochralski, fully encapsulated Czochralski and hot-wall Czochralski. The reader is referred to the reference for more details of these techniques.

Fig. 12.13 Schematic of liquid-encapsulated Czochralski growth equipment. A silica outer vessel with viewing port is held between end-plates. The induction heating coils couple into the graphite surround. The seed is fixed in the chuck on the pull rod that rotates and moves through the bearing and seal. The crystal grows from the seed through a necking process, and on withdrawal pulls out a layer of B_2O_3 over its surface. (After [12.44]; copyright Wiley-VCH (1998), used with permission)

An alternative to Czochralski is that of vertical gradient freeze. For reproducible growth of large-diameter crystals by this technique, it was found necessary to use B_2O_3 in a PBN crucible. Freezing is accomplished by moving the temperature gradient via furnace controller changes, rather than movement of the furnace itself. This naturally produces low temperature gradients, which give low dislocation densities, and it produces a crystal of the right size and shape for subsequent slicing and processing. *Rudolph* [12.66] reports that in 1999 LEC growth of GaAs accounted for $\approx 90\%$ of all SI GaAs, with the remaining 10% produced via vertical Bridgman or VGF growth. By 2000, he puts the figures at $\approx 50\%$ LEC and $\approx 50\%$ VGF. *Rudolph* also notes that VGF has been reported to grow material up to 150 mm in diameter.

Indium and Gallium Phosphides

As for GaAs, high-pressure LEC growth is normally used for both InP and GaP [12.44]. The problems involved are analogous to those for GaAs growth, with the major addition of an increased tendency for twinning. Loss of phosphorus (P_4) is still a problem and leads to a deterioration in crystal quality. Dislocation densities are still seen to be high. *Asahi* et al. [12.67] report that some of these problems have been alleviated by modifications to the basic LEC process, such as thermal-baffled LEC, phosphorus vapor pressure controlled LEC, and vapor pressure controlled Czochralski (VCZ). Dislocations tend to increase with crystal diameter, although crystals up to 100 mm in size with low dislocation densities have been grown recently by VCZ. Lower dislocation densities are produced by the VGF method at a given crystal diameter. High-pressure VGF growth of InP is difficult and temperature fluctuations cause twinning. By improving the temperature control (to within $\pm 0.03^\circ\text{C}$) *Asahi* et al. have shown that twin-free (100) InP single crystals 100 mm in diameter and 80 mm in length can be obtained. Temperature gradients of $< 10^\circ\text{C}/\text{cm}$ reduced the etch pit densities to below those of comparable LEC material.

Indium and Gallium Antimonides

Mullin [12.44] has detailed the early work on InSb; much less work has been done on GaSb. The low melting point combined with the negligible vapor pressure of Sb over the melt make zone-refining methods attractive. However, certain impurities render this route troublesome, although ways of overcoming this issue were found. Crystal-pulling methods were preferred for their versatility, although twinning was

seen as a major issue. Growth on the (111)Sb face produces this twinning and it is recommended that growth should occur on the [211]Sb or [311]Sb faces instead.

Micklethwaite and *Johnson* [12.68] have summarized the current status of the production of InSb for IR detector applications. InSb expands by $\approx 13\%$ on freezing, leading to a net flow away from the growth interface. This ‘density effusion’ must be accounted for when modeling this system. Hydrogen is used as the atmosphere, as it reduces floating InO_x . The basic Czochralski method is used for commercial production and diameters of 75 mm are routine. Defect densities can be as low as 10 cm^{-2} . Many of the details of the growth process are proprietary. Growth proceeds without a liquid encapsulant, and as such resembles Si growth more closely than its arsenide and phosphide cousins. However, there are significant differences from the silicon case in terms of reduced radiative heat transfer and increased convective flow in the hydrogen atmosphere. Fluid mechanics in the melt are complicated by both ‘density effusion’ and the facet effect [12.44].

Bridgman growth is not used for InSb growth any longer, but float-zone growth has been achieved in microgravity conditions using an oxide ‘skin’ for containment.

Group III Nitrides

There has been a rapid increase in the interest in these compounds following the successful development of blue laser diodes. Ideally, epitaxial thin films of these nitrides would be grown on bulk substrates of similar compounds, to minimize lattice mismatch. However, growth of these compounds by the more normal Czochralski and Bridgman techniques is not possible due to the high melting temperatures (2200–3500 K) and high decomposition pressures (0.2–60 kbar) [12.69, 70]. One growth method that can be used is high-pressure solution growth. In this technique, liquid Ga (plus 0.2–0.5 at.% Mg, Ca, Be or Zn) is held in a high-pressure chamber with a N_2 atmosphere. The maximum pressure is ≈ 20 kbar and the maximum temperature is 2000 K. Both pressure and temperature are controlled within tight limits and in situ annealing in vacuum is also allowed for. A temperature gradient of $2\text{--}20^\circ\text{C}/\text{cm}$ is maintained along the crucible axis and the N_2 dissolves in the hotter end and GaN crystallizes in the cooler end. No seeding was used and after 120–150 hours of growth hexagonal needles or platelets are produced of size 10×10 mm. Growth by MOVPE and MBE of GaN and InGaN MQWs on these bulk GaN samples was also re-

ported by Grzegory et al. [12.70]. LEDs and laser diodes based on these epitaxial layers were also described.

This technique only produces very small crystals of both AlN and InN.

Nishino and Sakai [12.71] describe the sublimation growth of both GaN and AlN. Initially, the source powder is synthesized by heating Ga metal in NH_3 . This powder is then annealed in NH_3 before loading into the growth chamber. Temperatures are 1000–1100 °C but atmospheric pressure can now be employed. Both NH_3 and N_2 are introduced into the growth chamber. Either small (3 mm \times several hundred μm) ‘bulk’ crystals or free-standing films (10–30 μm thick) on sapphire substrates are produced. Thicker samples (up to 500 μm thick) can be produced by the sublimation sandwich method in which the distance from the source to substrate is reduced to 2–5 mm. A hot-pressed polycrystalline source of AlN and a SiC-coated graphite crucible was used to grow 0.3–1.0 mm-thick films on the 6H-SiC seed (10 \times 10 mm in size) at temperatures of 1950–2250 °C.

12.3.3 Groups II–VI

Several recent reviews of the growth of a wide range of binary and ternary II–VI compounds have been published [12.44, 58, 72, 73]. One of the key concepts in the growth of these compounds is the ease with which phase transitions occur. This imposes limits on certain growth techniques for particular compounds.

There are two main types of bulk growth technique, namely growth from the liquid and growth from the vapor. Most narrow-gap II–VI compounds are characterized by high melting points and/or high component partial pressures, and early work concentrated on various forms of vapor growth, particularly for S- and Se-containing compounds. Problems with low growth rates and/or small crystal sizes and purities led to a switch to melt growth techniques, although there have been some recent significant developments in the growth of larger crystals from the vapor.

Many techniques have been used to grow narrow-gap II–VI compounds. Solid state recrystallization (SSR) is used for ternary systems where there is a wide separation between solidus and liquidus, such as MCT. Other names that have been used for this process are quench anneal (QA) and cast recrystallize anneal (CRA). The term anneal is used in the first case to define a high-temperature grain growth process, while in CRA it is a low-temperature process used to adjust stoichiometry. Strictly speaking, SSR is crystal growth from the

solid phase at temperatures close to the melting point, but it is included here for convenience. In the basic technique, pure elements are loaded into a cleaned silica ampoule and the charge is melted and rocked to ensure complete mixing. Charges are then normally quenched rapidly, into air or oil, to room temperature in the vertical orientation. This produces a dendritic structure that is reduced/removed by the recrystallization step, which proceeds at temperatures just below the melting point for many days. Grain growth occurs and micro-inhomogeneities in composition are removed. Care must be taken in the quenching stage to avoid pipes/voids that cannot be removed by the recrystallization step.

Bridgman growth is the most widely used of the bulk growth techniques applied to narrow-gap II–VI compounds. It is the only technique that has produced crystals of all the binary and ternary compounds studied. Numerous modifications have been applied to the basic process, but the three principal means of achieving growth are to move an ampoule through a temperature gradient, to move the furnace past a stationary ampoule and to move a temperature profile from high to low temperatures with both the furnace and ampoule stationary, the so-called vertical gradient freeze (VGF) method.

Silica ampoules are usually used but various coatings have been applied, and the use of other materials such as PBN has been reported [12.74]. Charges are prepared either using the appropriate elements or, for ternaries and quaternaries, preformed compounds of the binaries. Both vertical and horizontal configurations have been used and large crystal sizes coupled with a relatively high growth rate (1–2 mm/h) make the basic technique relatively cheap and versatile. Marked segregation of both matrix elements in ternaries and quaternaries and impurities can occur. Difficulties with controlling component vapor pressures can be overcome by employing a reservoir of one of the components at a temperature lower than that of the growing crystal. High partial pressures in Hg-containing compounds can cause ampoule failure and ways have been developed to cope with this situation [12.75].

The traveling heater method (THM) has mainly been used for Te-based binary and ternary compounds. Growth by THM combines the advantages of low-temperature solution growth with steady-state conditions, as in zone melting. A homogeneous alloy can be used as the starting ingot, or segments of the binaries can be employed. If the Te zone height is made equal to the ring-heater size, then a flat interface is obtained for particular geometries of crystal and furnace and growth parameters [12.76]. Very low growth rates (0.1 mm/h)

are typical, but diameters of up to 40 mm have been accomplished. As in Bridgman, many variations on the basic THM method have been attempted. These include multipass THM [12.77] and ‘cold’ THM [12.78].

Hydrothermal growth has mainly been applied to S- and Se-based binary compounds and has been reviewed by Kuznetsov [12.79]. The main advantages are that it reduces growth temperature (to 200–250 °C) and that it deals with the high partial pressures. Growth rates are very low (0.05 mm/d), and crystals are small (few mm) and contain subgrains and inclusions, but can still provide useful fundamental data.

Growth from the vapor is usually carried out at much lower temperatures than growth from the liquid, below unwanted phase transition temperatures, and can lead to less defective crystals. However, growth rates are generally much lower and uncontrolled nucleation and twinning are more prevalent. Techniques can be split essentially into unseeded and seeded methods. The simplest technique is that of chemical vapor transport (CVT), usually using iodine as the transport agent. The compound to be grown is reacted at a high temperature with the iodine, transported to a cooler region and deposited. The reverse reaction produces iodine, which diffuses back to the high-temperature region and the process repeats itself. The method uses a two-zone furnace but has the disadvantages of iodine incorporation and small crystal sizes. Mimila and Triboulet [12.80] have experimented with sublimation and CVT using water as a transporting agent for ZnSe, and Triboulet (private communication, 1996) has succeeded in growing CdTe using this method.

Most other vapor techniques are in some sense a derivative of the Piper–Polich method (Fig. 12.12b). Although this was developed originally for the growth of CdS [12.81], the technique may be applied to the vapor growth of any compound that sublimates readily below the melting point temperature. The crystal is grown in a closed crucible that is moved through a steep temperature gradient, such that the source material is always hotter than the growing surface and mass transport occurs from source to crystal.

Vapor growth under the controlled partial pressure of one of the constituents has been obtained by including small quantities of one of the elements in an extended part of the capsule located in a cooler part of the furnace [12.82]. The technique, termed ‘Durham’, is a vertical unseeded growth procedure, where the source is sublimed from bottom to top in an evacuated silica capsule over several days. Constituent partial pressures are independently controlled by placing one of the ele-

ments in a separately heated reservoir connected to the main capsule via a small orifice.

The vertical unseeded vapor growth (VUVG) method differs from the Durham technique in that the partial pressures are controlled by the initial deviation from stoichiometry of the charge material. It was initially developed to grow CdTe. The crystal is grown in an evacuated cylindrical silica capsule in a vertical furnace. A long quartz tube, which extends outside the furnace, is attached to the top of the capsule, providing a heat pipe to create a cooler area for nucleation, which is closely monitored to ensure that the nucleus is single-grained. If it is not, then the capsule is returned to the starting position and the process repeated.

The sublimation traveling heater method (STHM) was developed from THM by Triboulet and Marfaing [12.77]. The Te-rich molten zone in conventional THM is replaced by an empty space or vapor zone. A problem arises in that the constituent partial pressures are not only functions of the temperature. However, the vapor can be maintained near the stoichiometric P_{\min} condition if a small capillary, one end of which is at room temperature, is connected to the vapor chamber [12.83]. Excess species are sublimed down the capillary, preserving the relative constituent partial pressures and hence the growth rate.

In one version of the seeded technique, an oriented seed is placed on top of a long sapphire rod inside a sealed quartz capsule. The source material is placed in a basket above the seed and sublimation is top-down. The sapphire rod is carefully centered within the growth capsule to ensure a narrow gap between it and the walls of the capsule. Crystals are grown in vacuum or in about 200 Torr of Ar, H₂ or NH₄I. The crystals grow clear of the container walls and generally consist of two or three large grains, some of which maintain the seed orientation. This ‘Markov’ technique has been adapted for commercial production by the ELMA Research and Development Association of Moscow (cited in Durose et al. [12.84]). The seed is mounted on an optically heated sapphire rod heat pipe, in a continuously pumped chamber, which can be back-filled with He to control growth rate. Large crystals of CdTe, 50 mm in diameter and up to 10 mm in length have been grown.

It is clear that HgS is grown by vapor means or by hydrothermal techniques, both of which are at low temperatures and hence low S partial pressures. HgSe has been produced by vapor growth and also by the Bridgman technique. Thick-walled silica ampoules are required in the growth of the Hg-containing compounds to contain the high Hg partial pressures. More details on

the growth of Hg-based binaries can be found in [12.78] for vapor and Bridgman growth, while *Kuznetsov* has reviewed the hydrothermal growth of HgS [12.79].

Early work on the growth of the Cd-based binaries was summarized by *Lorenz* [12.85]. Vapor growth was favored for CdS and CdSe, although hydrothermal growth was also discussed. The latter technique, as applied to CdS, was discussed in [12.79]. CdTe was grown by various melt growth techniques, including seeded zone melting and Bridgman, and by vapor growth methods. *Zanio* [12.86] has given a review of the growth, properties and applications of CdTe, including radiation detectors. By that time, vapor growth had been essentially supplanted by both Bridgman and THM growth. A more recent review of CdTe can be found in *Capper* and *Brinkman* [12.87]. The main uses of CdTe (and CdZnTe/CdTeSe) are as a substrate material for the epitaxial growth of MCT and, more recently, as radiation detectors [12.88]. *Triboulet* et al. [12.89,90] applied SSR to the growth of both CdSe and CdTe. The prime reasons for the use of this technique were the high melting point of CdSe and the solid-state phase transitions in the case of CdTe.

A wide variety of growth techniques from the liquid have been used to produce crystals of CdTe. These include solvent evaporation [12.91], liquid encapsulated Czochralski [12.92], zone refining [12.93], VGF [12.94,95], solution growth [12.96], heat exchanger method [12.97], float-zoning [12.98], Bridgman [12.87] and THM [12.47], and *Triboulet* et al. [12.89] have reviewed these materials as substrates for MCT epitaxial growth and compared them to the alternatives based on GaAs, sapphire and Si. Problems with the growth of CdTe include low thermal conductivity, difficulty in seeding due to the need for superheated melts, ease of twin formation, tilts and rotations in the lattice, stoichiometry control and impurities. However, *Triboulet* et al. [12.90] concluded that despite the progress made in the alternative substrate materials, lattice-matched substrates based on CdTe produced MCT epitaxial layers that gave the best device performance.

Within the Bridgman growth technique, many alternatives have been attempted. These include holding excess Cd at a lower temperature in a separate reservoir [12.99], vibration-free growth [12.100], vibrational stirring [12.101], horizontal growth [12.102], low temperature gradients [12.103], high-pressure (100 atm) growth [12.104] and the addition of the accelerated crucible rotation technique (ACRT) [12.105]. Work in the US [12.102] aimed at improving both the horizontal and

vertical techniques and scaling-up to large melts, up to 8 kg (horizontal). Recent work by *Szeles* et al. [12.106] has shown that crystals up to 140 mm in diameter and 10 kg in weight can be grown by careful control of the temperature fields.

In the Bridgman process, elemental Cd and Te are loaded into a clean carbon-coated silica ampoule, homogenized by melting/rocking, heated to temperatures in excess of 1100 °C, and then frozen at rates of a few mm/h in a vertical or horizontal system. Single crystals or, more normally, large-grained ingots of size ≈ 75 mm in diameter and 10–15 cm in length are produced. Seeding on the (111) is often utilized but it is not clear that it results in better growth in every case.

Growth by variations on the basic THM process have included the addition of ACRT [12.107,108], focused radiant heating [12.109], sublimation THM and multipass THM [12.77] and ‘cold’ THM at 780 °C [12.78]. Crystals are grown either from the pre-compounded binaries or from the elements (as in cold THM). Growth rates tend to be low, a few mm/d, but the crystals are very pure due to segregation effects and high-resistivity material results ($10^7 \Omega \text{ cm}$ in [12.77]). This makes THM material ideally suited for gamma and X-ray detectors.

The vast majority of work on bulk growth of MCT has been from the melt. Although rapid progress has taken place in epitaxial growth techniques for MCT, material grown by several bulk methods is still in use for infra-red detection, particularly for photoconductive detectors (this is the case in this author’s lab and various others worldwide, such as AIM in Germany). Several historical reviews of the development of bulk MCT have been published [12.110–112]. Many techniques were tried in the early years but three prime techniques survived: SSR, Bridgman and THM.

Two fundamentally different approaches have been followed to improve the basic Bridgman process. These are based on controlling melt mixing and heat flows, respectively. The former has been studied by this author and coworkers [12.113] while the latter includes the work of *Szofran* and *Lehoczky* [12.114], among others. In the Bridgman process, elemental Cd, Hg and Te are loaded into a clean silica ampoule, homogenized by melting/rocking and then frozen slowly from one end in a vertical system to produce a single crystal or, more normally, a largegrained ingot. Marked segregation of CdTe with respect to HgTe occurs in the axial direction, but this leads to an advantage of the Bridgman process over other techniques: material in both ranges of interest (3–5 and 8–12 μm , for $x = 0.3$ and 0.2, respectively) is produced in a single run.

A means of stirring melts contained in sealed, pressurized ampoules was needed and the **ACRT** of *Scheel* and *Schulz-Dubois* [12.41], in which the melt is subjected to periodic acceleration/deceleration at rotation rates of up to 60 rpm, was chosen. The first report of **ACRT** in **MCT** Bridgman growth was given in a patent [12.115]. These effects were developed and discussed in more detail in later papers, which are reviewed in [12.113]. Crystals were produced up to 20 mm in diameter and with x values of up to 0.6 in the tip regions of some crystals (this has recently been increased to ≈ 0.7 at 20 mm diameter in the author's laboratory [12.42, 116]).

Triboulet [12.47] developed this technique for **MCT**, where diameters of up to 40 mm have been accomplished as well as x values of up to 0.7 [12.117] for optical communication devices. *Durand* et al. [12.118] employed seeds to produce large, oriented crystals, an advantage of this technique over other bulk methods. *Gille* et al. [12.119] adopted a slightly different approach. A pre-**THM** step is carried out to quench a Te-rich (53–60%) **MCT** melt. A first **THM** run at 2 mm/d is then used to provide the source ingot, after removal of the tip and tail sections, for the final **THM** run. The entire growth procedure takes several months but gives uniform material. This group has also used rotation in the horizontal growth by **THM** with some success [12.120]. Attempts to use 'cold' **THM** (starting from the elements) led to little success for **MCT** nor did use of a Hg reservoir to control the process. Two groups have applied **ACRT** to **THM** and obtained enhanced material properties. *Royer* et al. [12.121] used a saw-tooth **ACRT** sequence and obtained improved radial and axial compositional uniformity. *Bloedner* and *Gille* [12.122] used **ACRT** although no significant dependence of crystallinity on rotation sequence was seen. They achieved an increase in growth rate from 1.5 to 8.5 mm/d.

Bridgman is the main melt growth technique for the Hg- and Cd-based ternary and quaternary compounds, while work on the vapor growth of these compounds has been limited. The various Hg-based ternaries (such as HgZnTe and HgMnTe) have been studied as potential alternatives to **MCT** for infrared detectors (*Rogalski* [12.123] has more details including phase equilibria plots). This work was initiated by a theoretical prediction that the Hg–Te bond is stabilized by the addition of Zn, in particular. *Rogalski* concluded that **THM** produced the best quality HgZnTe while Bridgman growth of HgMnTe was described as being similar to **MCT** growth but with reduced segregation. Crystals of HgMnTe up to 40 mm in diameter were produced.

Triboulet [12.124] has discussed alternatives to **MCT**. He concluded that HgMgTe, HgCdSe and HgZnSe are not suitable, for a variety of reasons, but that HgMnTe and HgZnTe are potentially suitable.

The main Cd-based ternaries are CdZnTe and CdTeSe, which are used as substrates for epitaxial **MCT** growth. A vast literature exists on these compounds and it is still a very active area of research. Vertical and horizontal Bridgman are the main techniques used [12.87], although **VGF** has been used [12.87], as has **THM** [12.47]. High-quality crystals up to 100 mm (and even 125 mm) in diameter can be produced by **VGF** [12.67, 95]. Even larger crystals are being grown by horizontal Bridgman [12.106, 125]. Two main problems remain in these compounds. These are the uniformity of Zn or Se, and impurities.

Recent reports by *Pellicciari* et al. [12.126] have shown how solvent evaporation from a Te-rich solution of CdTe in an open tube system can produce large-grained and even single crystals of CdTe up to 300 mm in diameter. This large-area material is aimed at the fabrication of X-ray and γ -ray detectors.

Dilute magnetic semiconductors (**DMSs**) are a class of semiconductor where the semiconducting properties are changed through the addition of a magnetic ion (such as Mn^{2+} or Fe^{2+}). These materials therefore display normal electrical and magnetic properties, and novel ones such as large Faraday rotations and giant magnetoresistance. *Pajaczowska* [12.127] gave an early review of the phase diagrams, lattice parameters and growth of many of the Mn- and Fe-based **DMS** compounds. Vapor growth and hydrothermal growth were mainly used, although the Te-based compounds were being grown by the Bridgman technique. Only small additions of the magnetic ions are required, so essentially the same techniques can be used as those applied to the parent binaries. The most comprehensive review of **DMSs** is given in [12.128]. In that book, *Giriat* and *Furdyna* review the crystal structures of, and growth methods used for, the Mn-based compounds. The majority of the compounds, particularly the Te-based ones, were grown using Bridgman or unspecified modifications of it. CdMnS was grown in graphite crucibles under high inert gas pressure, or by chemical vapor transport (using iodine as the transport agent). HgMnS was grown hydrothermally, yielding 2 mm-diameter crystals. Similar preparation methods to those used for the Mn-based compounds were applied for Fe-based compounds, but less Fe can be incorporated in the lattice.

Bismuth telluride (strictly speaking a V–VI compound) is used in thermoelectric applications close to

room temperature [12.129]. This material is also grown by the Bridgman technique. Both n-type and p-type materials are required to make the thermoelectric devices, and these can be achieved either by stoichiometric deviations or deliberate doping. Typical growth rates are 0.5–2.9 mm/h for 8 mm-diameter ingots of up to 85 mm length. In this author's lab, bismuth telluride is grown at similar rates for 12 mm-diameter ingots up to 100 mm length using antimony and iodine as acceptor and donor dopants, respectively.

12.3.4 Oxides/Halides/Phosphates/Borates

Oxides

Hurle [12.43] summarized issues concerning the growth of oxides by the Czochralski technique. The high melting points of most oxides of interest necessitate the use of precious metal crucibles, such as iridium or platinum, although molybdenum and tungsten ones can be used for lower melting point materials. Extensive and efficient thermal insulation is required, using alumina, magnesia, zirconia and thoria. Some materials require a partial pressure of oxygen in the growth chamber to prevent reduction of the melt. However, this can lead to oxidation of the crucible, which in turn enters the melt. Careful management of the oxygen pressure and gas flow is needed, together with physical baffles. Heating is normally by means of RF. Mounting of the seeds is problematic and long seeds are necessary to avoid thermal degradation of the seed holder and pull rod. Rotation or translation of the crucible is not normally used so the rate of growth has to be above the pulling rate to account for the fall in melt height. Crystals are normally limited to less than half the crucible diameter for stable growth. Growth rates are low, a few mm/h or less, to avoid unstable growth. Afterheaters are also employed to reduce the built-in stress in the crystal during the later stages of growth and subsequent cool-down. Growth runs extend over several days, so automatic diameter control, in this instance using weighing techniques, is mandatory. The high temperatures lead to high temperature gradients and thus strong buoyancy-driven convection that is turbulent by nature. This turbulence gives rise to nonuniformities in the crystals. In addition, catastrophic failure can result due to the coupling between this turbulent flow and the flow due to the crystal rotation. Thus, an understanding of the convective flows present during oxide growth is critical if large-diameter highly perfect crystals are to be produced.

More recently, *Fukuda* et al. [12.130, 131] have presented detailed reviews of the growth of a wide

range of oxide materials of current interest for optical and optoelectronic applications. They firstly note that only LiNbO_3 (LN), LiTaO_3 (LT) and $\text{Y}_3\text{Al}_5\text{O}_{12}$ (YAG) have as yet reached production status. Many of the other materials exhibit superior properties but are not available in large quantities at sufficient perfection to warrant them being used in devices. Recently, crystals of new nonlinear optical materials, piezoelectric materials and new laser materials have attracted growing interest. In general, the growth methods are based on liquid–solid transitions, either from the melt or from high-temperature solutions (flux), for congruently and incongruently melting materials, respectively. Czochralski growth is still the mainstay of oxide growth, although problems with shape (diameter) control of some oxides (including rare earth vanadates and rutile) necessitate the use of edge-defined film-fed growth (EFG). Growth from fluxes is used for a range of oxide materials, although some incongruently melting materials can be produced from melts of the same composition as the crystal by a micro-pulling down technique.

In the micro-pulling down technique, the melt is held in a Pt crucible and a micronozzle (die) is arranged at the bottom of the melt. An after heater is placed below this arrangement. This combination produces a steep temperature gradient (300 °C/mm), which ensures stable growth at high rates. Single crystals of 0.05–1.0 mm diameter are produced onto seeds. LN crystals, for example, are grown at 12–90 mm/h from stoichiometric melts up to 100 mm in length, assumed to be limited only by the melt volume used. Dislocations are introduced if the diameter of the crystal exceeds 0.8 mm. Growth of $\text{K}_3\text{Li}_2\text{Nb}_5\text{O}_{12}$ (KLN), which has outstanding electro-optic and nonlinear optical properties, is problematic by either Czochralski or Kyropoulos methods due to segregation effects at the solid/liquid interface and cracking. This material was grown by the micro-pulling down technique at rates of 20–80 mm/h with diameters of 0.15–0.5 mm. The crystal composition was found to be near to the melt composition and crystals were single-domain.

Crystals in the KTiOPO_4 (KTPO) family were grown by the flux method using slow-cooling from 1100 to 800 °C. Crystals a few millimeters in size were obtained for second harmonic-generation measurements.

Crystals from the langasite family ($\text{La}_3\text{Ga}_3\text{SiO}_{12}$) are used for lasers. These were grown by the Czochralski method to 50 mm in diameter and 130 mm in length. High-purity oxide powders were used as starting materials and an Ar/O_2 mixture was used to suppress evaporation of the gallium suboxide. A pulling rate of

1.0 mm/h was used together with a crystal rotation rate of 10 rpm. The resulting crystals were single-phase and crack-free. These crystals show superior properties, as filters, to quartz. Crystals of up to 100 mm in diameter have been grown recently [12.132].

Both rare earth vanadates and some garnet crystals show a tendency toward spiral growth when the Czochralski method is used. This tendency can be circumvented by adjusting the temperature gradient in the melt.

Another way of overcoming problems with the Czochralski growth of these materials is to use the EFG method. Rutile (TiO_2) is used as a polarizer in optical isolators and prisms for optical communication systems. Crystals of this material can be grown by Verneuil and float-zone methods, but growth by Czochralski is difficult. Iridium is used for the die material and crystals up to 8×1 cm and 0.5 mm thick were grown. A modified die was used to grow a rod of 15 mm diameter and ≈ 40 mm in length. A double-die system was shown that was used to produce a core-doped crystal of LN, using Nd^{3+} and Cr^{3+} as the dopants. A 5 mm-diameter crystal some 60 mm in length was produced. Such crystals have potential in optical applications where pumping energy is only absorbed in the core region, reducing heat-induced energy losses.

Quartz is used in both piezoelectric and in various optical applications [12.133]. *Balitsky* [12.134] noted that some 2500 t are produced per year. Hydrothermal growth is the main growth technique used in order to keep the growth temperature below the β - (non-piezoelectric) to α -quartz (piezoelectric) phase transition. Growth at temperatures of 250–500 °C and pressures of 50–200 MPa are used in both alkaline and fluoride solutions. Growth rates of 0.5–1.0 mm/d are achieved on (0001) or (1120) seeds and crystals up to $200 \times 70 \times 60$ mm in size weighing from 1–18 kg.

Various oxide materials are used widely in scintillator applications. The most common are $\text{Bi}_4\text{Ge}_2\text{O}_{12}$ (BGO) and PbWO_4 (PWO) [12.135, 136]. These materials are grown by normal Czochralski and Bridgman techniques and the requirement is for thousands of each for large high-energy/astrophysics projects in several centers throughout the world. For example, some 85 000 PWO crystals are required for one application at the Large Hadron Collider at CERN. High-purity starting materials are important, as are certain growth parameters and post-growth annealing, for example in oxygen, to reduce stress in the material.

Sapphire is grown by several techniques for a wide variety of optical, microwave and microelectronics ap-

plications [12.137]. Verneuil [12.138], Czochralski and EFG [12.43] have been used extensively to produce large single crystals, particularly for laser rods, and shaped pieces using various forms of dies. In addition, the horizontal directional solidification crystallization (HDC) technique [12.137] has been used as it is a simple and inexpensive technique to set up and use. A molybdenum boat filled with the charge is simply moved through the temperature gradient. Low temperature gradients lead to crystals with low stress and low dislocation densities (compared with the Verneuil and pulling techniques. The growth rate is high at 8 mm/h, and crystals of up to 10 kg and up to $30 \times 30 \times 2.5$ cm are produced. Even larger crystals, up to 20 kg with a diameter of 200 mm, can be produced by a modified Kyropolous method [12.139].

Another technique used is the heat exchanger method, which is a solidification technique from the melt [12.140]. Large crystals can be grown onto seeds by independently controlling the heat input and the heat output. The seed is prevented from melting by a helium gas flow at the bottom of the melt. By progressively increasing the helium flow, following partial melting of the seed, and/or decreasing the furnace temperature, growth is progressed. After complete solidification, an annealing step is performed prior to cooling to room temperature. The submerged solid/liquid interface damps out any thermal and mechanical variations and also produces a low temperature gradient at the interface. There is impurity segregation into the last-to-freeze parts of the crystal that form near the crucible walls. These areas are removed before machining takes place. Crystals up to 340 mm in diameter (65 kg) have been produced in this way. Slabs cut from these crystals are used as optical windows, between 5–25 mm thick.

Halides

Several halides form another class of scintillator materials. These are used in a range of applications, from high-energy physics and nuclear medicine to environmental monitoring and security systems [12.141]. Both large diameters (comparable with the human body) and large numbers are required for high-energy physics applications. The simple Bridgman growth process is still used for many of these materials, although problems do arise due to the contact between crystal and crucible. Insufficient melt mixing also leads to inclusions and striations in crystals. The alternative technique for growth is that of continuously fed Czochralski/Kyropolous growth. A melt-level sensor is normally used to control the diameter over the tens/hundreds of hours of growth needed for large halide crystals. Replenishment

of the melt by molten material from a closed feeder enables the starting materials to be purified, and a conical crucible that is not too deep is used. Crystals of CsI up to 500 mm in diameter and 750 mm in height weighing ≈ 550 kg have been produced [12.142]. The ultimate aim is to produce crystals > 1 m in diameter so that entire crystals can be used to monitor the human body.

Phosphates and Borates

Nonlinear optical materials are very important for laser frequency conversion applications. One of the most important of the phosphates is potassium dihydrogen phosphate (KDP), which is used for higher harmonic generation in large laser systems for fusion experiments [12.94, 143]. Growth takes place at room

temperature to 60°C , and growth rates can be as high as 10–20 mm/day, with sizes of $\approx 40\text{ cm} \times 40\text{ cm} \times 85\text{ cm}$ [12.143] or $45\text{ cm} \times 45\text{ cm} \times 70\text{ cm}$ [12.94], the latter quoted as taking over a year to grow!

Another important phosphate is potassium titanyl phosphate (KTP), used to obtain green light by frequency doubling a Nd:YAG laser. Growth in this case is from high-temperature solution at about 950°C [12.94]. Sizes of up to $32\text{ mm} \times 42\text{ mm} \times 87\text{ mm}$ (weight 173 g) can be grown in 40 days.

Borates, including barium borate, lithium borate, cesium borate and coborates such as cesium lithium borate are used in UV-generation applications. Crystals are again grown by the high-temperature solution method up to $14\text{ cm} \times 11\text{ cm} \times 11\text{ cm}$ in size, weighing 1.8 kg, in 3 weeks [12.94].

12.4 Conclusions

This chapter has summarized the current status of the bulk growth of crystals for optoelectronic and electronic applications. It is not intended to be a completely comprehensive view of the field, merely serving to introduce the reader to the wide range of materials produced and the numerous crystal growth techniques that have been developed to grow single crystals. An historical perspective has been attempted to give the

reader a feel for the scale of some of the activities. The sections on specific materials try to summarize the particular growth techniques employed, and those that cannot in some cases, and outline the typical sizes currently produced in the commercial and R&D sectors. For more details on current developments, the reader should refer to the books given in references [12.42, 60].

13. Single-Crystal Silicon: Growth and Properties

It is clear that silicon, which has been the dominant material in the semiconductor industry for some time, will carry us into the coming ultra-large-scale integration (ULSI) and system-on-a-chip (SOC) eras, even though silicon is not the optimum choice for every electronic device. Semiconductor devices and circuits are fabricated through many mechanical, chemical, physical, and thermal processes. The preparation of silicon single-crystal substrates with mechanically and chemically polished surfaces is the first step in the long and complex device fabrication process. In this chapter, the approaches currently used to prepare silicon materials (from raw materials to single-crystalline silicon) are discussed.

13.1	Overview	256
13.2	Starting Materials	257
13.2.1	Metallurgical-Grade Silicon	257
13.2.2	Polycrystalline Silicon	257
13.3	Single-Crystal Growth	258

Silicon, which has been and will continue to be the dominant material in the semiconductor industry for some time to come [13.1], will carry us into the ultra-large-scale integration (ULSI) era and the system-on-a-chip (SOC) era.

As electronic devices have become more advanced, device performance has become more sensitive to the quality and the properties of the materials used to construct them.

Germanium (Ge) was originally utilized as a semiconductor material for solid state electronic devices. However, the narrow bandgap (0.66 eV) of Ge limits the operation of germanium-based devices to temperatures of approximately 90 °C because of the considerable leakage currents observed at higher temperatures. The wider bandgap of silicon (1.12 eV), on the other hand, results in electronic devices that are capable of operating at up to $\approx 200^\circ\text{C}$. However, there is a more serious problem than the narrow bandgap: germanium does not readily provide a stable passivation layer on the surface. For example, germanium dioxide (GeO_2) is water-soluble and dissociates at approximately 800 °C. Silicon, in contrast to germanium, readily accommo-

dates surface passivation by forming silicon dioxide (SiO_2), which provides a high degree of protection to the underlying device. This stable SiO_2 layer results in a decisive advantage for silicon over germanium as the basic semiconductor material used for electronic device fabrication. This advantage has lead to a number of new technologies, including processes for diffusion doping and defining intricate patterns. Other advantages of silicon are that it is completely non-toxic, and that silica (SiO_2), the raw material from which silicon is obtained, comprises approximately 60% of the mineral content of the Earth's crust. This implies that the raw material from which silicon is obtained is available in plentiful supply to the IC industry. Moreover, electronic-grade silicon can be obtained at less than one-tenth the cost of germanium. All of these advantages have caused silicon to almost completely replace germanium in the semiconductor industry.

Although silicon is not the optimum choice for every electronic device, its advantages mean that it will almost certainly dominate the semiconductor industry for some time yet.

13.1 Overview

Very fruitful interactions have occurred between the users and manufacturers of semiconductor material since the invention of the point-contact transistor in 1947, when the necessity for “perfect and pure” crystals was recognized. The competition was often such that the crystal quality demanded by new devices could only be met by controlling crystal growth using electronic equipment built with these new devices. Since dislocation-free silicon crystals were grown as early as the 1960s using the *Dash technique* [13.3], semiconductor material research and developmental efforts have concentrated on material purity, production yields, and problems related to device manufacture.

Semiconductor devices and circuits are fabricated using a wide variety of mechanical, chemical, physical and thermal processes. A flow diagram for typical semiconductor silicon preparation processes is shown

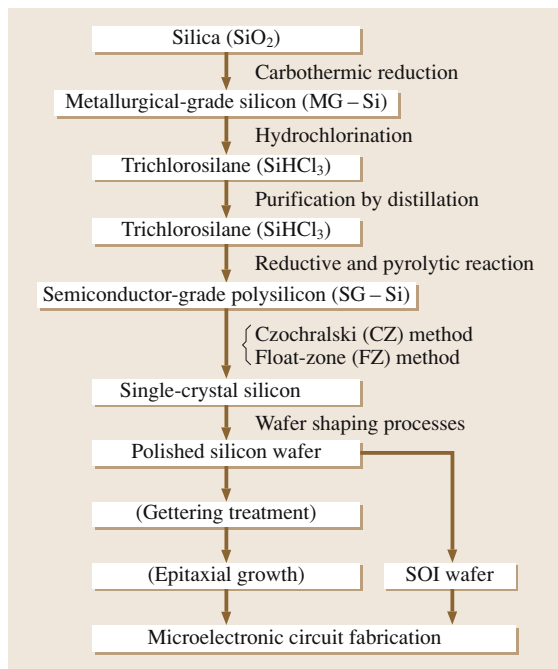

Fig. 13.1 Flow diagram for typical semiconductor silicon preparation processes. (After Shimura [13.1])

in Fig. 13.1. The preparation of silicon single-crystal substrates with mechanically and chemically polished surfaces is the first step in the long and complex process of device fabrication.

As noted above, silicon is the second most abundant element on Earth; more than 90% of the Earth’s crust is composed of silica and silicates. Given this boundless supply of raw material, the problem is then to transform silicon into the usable state required by the semiconductor technology. The first and main requirement is that the silicon used for electronic devices must be extremely pure, since very small amounts of some impurities have a strong influence on the electronic characteristics of silicon, and therefore the performance of the electronic device. The second requirement is for large-diameter crystals, since the chip yield per wafer increases substantially with larger diameters, as shown in Fig. 13.2 for the case of DRAM [13.2], one of the most common electronic devices. Besides the purity and the diameter, the cost of production and the specifications of the material, including the grown-in defect density and the resistive homogeneity, must meet current industrial demands.

In this chapter, current approaches to the preparation of silicon – converting the raw material into single-crystalline silicon (see Fig. 13.1) – are discussed.

Fig. 13.2 Chips per wafer as a function of DRAM generation. (After Takada et al. [13.2])

13.2 Starting Materials

13.2.1 Metallurgical-Grade Silicon

The starting material for high-purity silicon single crystals is silica (SiO_2). The first step in silicon manufacture is the melting and reduction of silica. This is accomplished by mixing silica and carbon in the form of coal, coke or wood chips and heating the mixture to high temperatures in a submerged electrode arc furnace. This carbothermic reduction of silica produces fused silicon:

A complex series of reactions actually occur in the furnace at temperatures ranging from 1500 to 2000 °C. The lumps of silicon obtained from this process are called metallurgical-grade silicon (MG-Si), and its purity is about 98–99%.

13.2.2 Polycrystalline Silicon

Intermediate Chemical Compounds

The next step is to purify MG-Si to the level of semiconductor-grade silicon (SG-Si), which is used as the starting material for single-crystalline silicon. The basic concept is that powdered MG-Si is reacted with anhydrous HCl to form various chlorosilane compounds in a fluidized-bed reactor. Then the silanes are purified by distillation and chemical vapor deposition (CVD) to form SG-polysilicon.

A number of intermediate chemical compounds have been considered, such as monosilane (SiH_4), silicon tetrachloride (SiCl_4), trichlorosilane (SiHCl_3) and dichlorosilane (SiH_2Cl_2). Among these, trichlorosilane is most commonly used for subsequent polysilicon deposition for the following reasons: (1) it can be easily formed by the reaction of anhydrous hydrogen chloride with MG-Si at reasonably low temperatures (200–400 °C); (2) it is liquid at room temperature, so purification can be accomplished using standard distillation techniques; (3) it is easy to handle and can be stored in carbon steel tanks when dry; (4) liquid trichlorosilane is easily vaporized and, when mixed with hydrogen, it can be transported in steel lines; (5) it can be reduced at atmospheric pressure in the presence of hydrogen; (6) its deposition can take place on heated silicon, eliminating the need for contact with any foreign surfaces that may contaminate the resulting silicon; and (7) it reacts at lower temperatures (1000–1200 °C) and at faster rates than silicon tetrachloride.

Hydrochlorination of Silicon

Trichlorosilane is synthesized by heating powdered MG-Si at around 300 °C in a fluidized-bed reactor. That is, MG-Si is converted into SiHCl_3 according to the following reaction:

The reaction is highly exothermic and so heat must be removed to maximize the yield of trichlorosilane. While converting MG-Si into SiHCl_3 , various impurities such as Fe, Al, and B are removed by converting them into their halides (FeCl_3 , AlCl_3 , and BCl_3 , respectively), and byproducts such as SiCl_4 and H_2 are also produced.

Distillation and Decomposition of Trichlorosilane

Distillation has been widely used to purify trichlorosilane. The trichlorosilane, which has a low boiling point (31.8 °C), is fractionally distilled from the impure halides, resulting in greatly increased purity, with an electrically active impurity concentration of less than 1 ppba. The high-purity trichlorosilane is then vaporized, diluted with high-purity hydrogen, and introduced into the deposition reactor. In the reactor, thin silicon rods called slim rods supported by graphite electrodes are available for surface deposition of silicon according to the reaction

In addition this reaction, the following reaction also occurs during polysilicon deposition, resulting in the formation of silicon tetrachloride (the major byproduct of the process):

This silicon tetrachloride is used to produce high-purity quartz, for example.

Needless to say, the purity of the slim rods must be comparable to that of the deposited silicon. The slim rods are preheated to approximately 400 °C at the start of the silicon CVD process. This preheating is required in order to increase the conductivity of high-purity (high-resistance) slim rods sufficiently to allow for resistive heating. Depositing for 200–300 h at around 1100 °C results in high-purity polysilicon rods of 150–200 mm in diameter. The polysilicon rods are shaped into various forms for subsequent crystal growth processes, such as chunks for Czochralski melt growth and long cylindrical rods for float-zone growth. The process for reducing

trichlorosilane on a heated silicon rod using hydrogen was described in the late 1950s and early 1960s in a number of process patents assigned to Siemens; therefore, this process is often called the “Siemens method” [13.4].

The major disadvantages of the Siemens method are its poor silicon and chlorine conversion efficiencies, relatively small batch size, and high power consumption. The poor conversion efficiencies of silicon and chlorine are associated with the large volume of silicon tetrachloride produced as the byproduct in the CVD process. Only about 30% of the silicon provided in the CVD reaction is converted into high-purity polysilicon. Also, the cost of producing high-purity polysilicon may depend on the usefulness of the byproduct, SiCl_4 .

Monosilane Process

A polysilicon production technology based on the production and pyrolysis of monosilane was established in the late 1960s. Monosilane potentially saves energy because it deposits polysilicon at a lower temperature and produces purer polysilicon than the trichlorosilane process; however, it has hardly been used due to the lack of an economical route to monosilane and due to processing problems in the deposition step [13.5]. However, with the recent development of economical routes to high-purity silane and the successful operation of a large-scale plant, this technology has attracted the attention of the semiconductor industry, which requires higher purity silicon.

In current industrial monosilane processes, magnesium and MG-Si powder are heated to 500°C under a hydrogen atmosphere in order to synthesize magnesium silicide (Mg_2Si), which is then made to react with ammonium chloride (NH_4Cl) in liquid ammonia (NH_3) below 0°C to form monosilane (SiH_4). High-purity polysilicon is then produced via the pyrolysis of the monosilane on resistively heated polysilicon filaments at $700\text{--}800^\circ\text{C}$. In the monosilane generation process, most of the boron impurities are removed from silane via chemical reaction with NH_3 . A boron content of 0.01–0.02 ppba in polysilicon has been achieved using a monosilane process. This concentration is very low compared to that observed in polysilicon prepared from trichlorosilane. Moreover, the

resulting polysilicon is less contaminated with metals picked up through chemical transport processes because monosilane decomposition does not cause any corrosion problems.

Granular Polysilicon Deposition

A significantly different process, which uses the decomposition of monosilane in a fluidized-bed deposition reactor to produce free-flowing granular polysilicon, has been developed [13.5]. Tiny silicon seed particles are fluidized in a monosilane/hydrogen mix, and polysilicon is deposited to form free-flowing spherical particles that are an average of $700\text{ }\mu\text{m}$ in diameter with a size distribution of 100 to $1500\text{ }\mu\text{m}$. The fluidized-bed seeds were originally made by grinding SG-Si in a ball or hammer mill and leaching the product with acid, hydrogen peroxide and water. This process was time-consuming and costly, and tended to introduce undesirable impurities into the system through the metal grinders. However, in a new method, large SG-Si particles are fired at each other by a high-speed stream of gas causing them to break into particles of a suitable size for the fluidized bed. This process introduces no foreign materials and requires no leaching.

Because of the greater surface area of granular polysilicon, fluidized-bed reactors are much more efficient than traditional Siemens-type rod reactors. The quality of fluidized-bed polysilicon has been shown to be equivalent to polysilicon produced by the more conventional Siemens method. Moreover, granular polysilicon of a free-flowing form and high bulk density enables crystal growers to obtain the most from each production run. That is, in the Czochralski crystal growth process (see the following section), crucibles can be quickly and easily filled to uniform loadings which typically exceed those of randomly stacked polysilicon chunks produced by the Siemens method. If we also consider the potential of the technique to move from batch operation to continuous pulling (discussed later), we can see that free-flowing polysilicon granules could provide the advantageous route of a uniform feed into a steady-state melt. This product appears to be a revolutionary starting material of great promise for silicon crystal growth.

13.3 Single-Crystal Growth

Although various techniques have been utilized to convert polysilicon into single crystals of silicon, two techniques have dominated the production of them for

electronics because they meet the requirements of the microelectronics device industry. One is a zone-melting method commonly called the *floating-zone (FZ) method*,

Fig. 13.3a,b Principles of single-crystal growth by (a) floating-zone method and (b) Czochralski method. (After Shimura [13.1])

and the other is a pulling method traditionally called the *Czochralski (CZ) method*, although it should actually be called the *Teal-Little method*. The principles behind these two crystal growth methods are depicted in Fig. 13.3. In the *FZ* method, a molten zone is passed through a polysilicon rod to convert it into a single-crystal ingot; in the *CZ* method, a single crystal is grown by pulling from a melt contained in a quartz crucible. In both cases, the *seed crystal* plays a very important role in obtaining a single crystal with a desired crystallographic orientation.

It is estimated that about 95% of all single-crystal silicon is produced by the *CZ* method and the rest mainly by the *FZ* method. The silicon semiconductor industry requires high purity and minimum defect concentrations in their silicon crystals to optimize device manufacturing yield and operational performance. These requirements are becoming increasingly stringent as the technology changes from LSI to VLSI/ULSI and then *SOC*. Besides the quality or perfection of silicon crystals, crystal diameter has also been steadily increasing in order to meet the demands of device manufacturers. Since microelectronic chips are produced via a “batch system,” the diameters of the silicon wafers used for device fabrication significantly affect the productivity (as shown in Fig. 13.2), and in turn the production cost.

In the following sections, we first discuss the *FZ* method and then move on to the *CZ* method. The lat-

ter will be discussed in more detail due to its extreme importance to the microelectronics industry.

13.3.1 Floating-Zone Method

General Remarks

The *FZ* method originated from zone melting, which was used to refine binary alloys [13.6] and was invented by *Theuerer* [13.7]. The reactivity of liquid silicon with the material used for the crucible led to the development of the *FZ* method [13.8], which permits the crystallization of silicon without the need for any contact with the crucible material, which is needed to be able to grow crystals of the required semiconductor purity.

Outline of the Process

In the *FZ* process, a polysilicon rod is converted into a single-crystal ingot by passing a molten zone heated by a needle-eye coil from one end of the rod to the other, as shown in Fig. 13.3a. First, the tip of the polysilicon rod is contacted and fused with a seed crystal with the desired crystal orientation. This process is called *seeding*. The seeded molten zone is passed through the polysilicon rod by simultaneously moving the single crystal seed down the rod. When the molten zone of silicon solidifies, polysilicon is converted into single-crystalline silicon with the help of the seed crystal. As the zone travels along the polysilicon rod, single-crystal silicon freezes at its end and grows as an extension of the seed crystal.

After seeding, a thin neck about 2 or 3 mm in diameter and 10–20 mm long is formed. This process is called *necking*. Growing a neck eliminates dislocations that can be introduced into newly grown single-crystal silicon during the seeding operation due to thermal shock. This necking process, called the *Dash technique* [13.3], is therefore fundamental to growing dislocation-free crystals and is used universally in both the *FZ* and the *CZ* methods. An X-ray topograph of the seed, neck and conical part of a silicon single-crystal grown by the *FZ* method is shown in Fig. 13.4. It is apparent that dislocations generated at the melt contact are completely eliminated by necking. After the conical part is formed, the main body with the full target diameter is grown. During the entire *FZ* growth process, the shape of the molten zone and the ingot diameter are determined by adjusting the power to the coil and the travel rate, both of which are under computer control. The technique most commonly used to automatically control the diameter in both the *FZ* and *CZ* methods employs an infrared sen-

Fig. 13.4 X-ray topography of seed, neck and conical part of floating-zone silicon. (Courtesy of Dr. T. Abe)

sor focused on the meniscus. The shape of the meniscus on a growing crystal depends on its angle of contact at the three-phase boundary, the crystal diameter, and the magnitude of the surface tension. A change in meniscus angle (and therefore crystal diameter) is sensed, and the information is fed back in order to automatically adjust the growth conditions.

In contrast with CZ crystal growth, in which the seed crystal is dipped into the silicon melt and the growing crystal is pulled upward, in the FZ method the thin seed crystal sustains the growing crystal, as does the polysilicon rod from the bottom (Fig. 13.3). As a result, the rod is balanced precariously on the thin seed and neck during the entire growth process. The seed and neck can support a crystal of up to a 20 kg so long as the center of gravity of the growing crystal remains at the center of the growth system. If the center of gravity moves away from the center line, the seed will easily fracture. Hence, it was necessary to invent a crystal stabilizing and supporting technique before long and heavy FZ silicon crystals could be grown. For large crystals, it is necessary to support the growing crystal in the way shown in Fig. 13.5 [13.9], particularly in the case of recent FZ crystals with large diameters (150–200 mm), since their weights easily exceed 20 kg.

Doping

In order to obtain n- or p-type silicon single-crystals of the required resistivity, either the polysilicon or the growing crystal must be doped with the appropriate donor or acceptor impurities, respectively. For FZ silicon growth, although several doping techniques have been tried, the crystals are typically doped by blowing a dopant gas such as phosphine (PH_3) for n-type silicon or diborane (B_2H_6) for p-type silicon onto the molten zone. The dopant gas is usually diluted with a carrier gas, such as argon. The great advantage of this method is that the silicon crystal manufacturer does not need to store polysilicon sources with different resistivities.

Since the segregation (discussed in the next subsection) of elemental dopants for n-type silicon is much less than unity, FZ crystals doped by the traditional method have radial dopant gradients. Moreover, since the crystallization rate varies in the radial direction on the microscopic scale, the dopant concentrations distribute cyclically and give rise to so-called *dopant striations*, resulting in radial resistivity inhomogeneities. In order to obtain more homogeneously doped n-type silicon, neu-

Fig. 13.5 Supporting system for floating-zone silicon crystal. (After Keller and Mühlbauer [13.9])

tron transmutation doping (NTD) has been applied to FZ silicon crystals [13.10]. This procedure involves the nuclear transmutation of silicon to phosphorus by bombarding the crystal with thermal neutrons according to the reaction

The radioactive isotope ^{31}Si is formed when ^{30}Si captures a neutron and then decays into the stable isotope ^{31}P (donor atoms), whose distribution is not dependent on crystal growth parameters. Immediately after irradiation the crystals exhibit high resistivity, which is attributed to the large number of lattice defects arising from radiation damage. The irradiated crystal, therefore, must be annealed in an inert ambient at temperatures of around 700°C in order to annihilate the defects and to restore the resistivity to that derived from the phosphorus doping. Under the NTD scheme, crystals are grown without doping and are then irradiated in a nuclear reactor with a large ratio of thermal to fast neutrons in order to enhance neutron capture and to minimize damage to the crystal lattice.

The application of NTD has been almost exclusively limited to FZ crystals because of their higher purity compared to CZ crystals. When the NTD technique was applied to CZ silicon crystals, it was found that oxygen donor formation during the annealing process after irradiation changed the resistivity from that expected, even though phosphorus donor homogeneity was achieved [13.11]. NTD has the additional shortcoming that no process is available for p-type dopants and that an excessively long period of irradiation is required for low resistivities (in the range of $1\text{--}10\ \Omega\ \text{cm}$).

Properties of FZ-Silicon Crystal

During FZ crystal growth, the molten silicon does not come into contact with any substance other than the ambient gas in the growth chamber. Therefore, an FZ silicon crystal is inherently distinguished by its higher purity compared to a CZ crystal which is grown from the melt – involving contact with a quartz crucible. This contact gives rise to high oxygen impurity concentrations of around $10^{18}\ \text{atoms}/\text{cm}^3$ in CZ crystals, while FZ silicon contains less than $10^{16}\ \text{atoms}/\text{cm}^3$. This higher purity allows FZ silicon to achieve high resistivities not obtainable using CZ silicon. Most of the FZ silicon consumed has a resistivity of between 10 and $200\ \Omega\ \text{cm}$, while CZ silicon is usually prepared to resistivities of $50\ \Omega\ \text{cm}$ or less due to the contamination from the quartz crucible. FZ silicon is therefore mainly used to fabricate semiconductor power devices that support reverse voltages

in excess of $750\text{--}1000\ \text{V}$. The high-purity crystal growth and the precision doping characteristics of NTD FZ-Si have also led to its use in infrared detectors [13.12], for example.

However, if we consider mechanical strength, it has been recognized for many years that FZ silicon, which contains fewer oxygen impurities than CZ silicon, is mechanically weaker and more vulnerable to thermal stress during device fabrication [13.13, 14]. High-temperature processing of silicon wafers during electronic device manufacturing often produces enough thermal stress to generate slip dislocations and warpage. These effects bring about yield loss due to leaky junctions, dielectric defects, and reduced lifetime, as well as reduced photolithographic yields due to the degradation of wafer flatness. Loss of geometrical planarity due to warpage can be so severe that the wafers are not processed any further. Because of this, CZ silicon wafers have been used much more widely in IC device fabrication than FZ wafers have. This difference in mechanical stability against thermal stresses is the dominant reason why CZ silicon crystals are exclusively used for the fabrication of ICs that require a large number of thermal process steps.

In order to overcome these shortcomings of FZ silicon, the growth of FZ silicon crystals with doping impurities such as oxygen [13.15] and nitrogen [13.16] has been attempted. It was found that doping FZ silicon crystals with oxygen or nitrogen at concentrations of $1\text{--}1.5 \times 10^{17}\ \text{atoms}/\text{cm}^3$ or $1.5 \times 10^{15}\ \text{atoms}/\text{cm}^3$, respectively, results in a remarkable increase in mechanical strength.

13.3.2 Czochralski Method

General Remarks

This method was named after J. Czochralski, who established a technique for determining the crystallization velocities of metals [13.17]. However, the actual pulling method that has been widely applied to single-crystal growth was developed by Teal and Little [13.18], who modified Czochralski's basic principle. They were the first to successfully grow single-crystals of germanium, 8 inches in length and 0.75 inches in diameter, in 1950. They subsequently designed another apparatus for the growth of silicon at higher temperatures. Although the basic production process for single-crystal silicon has changed little since it was pioneered by Teal and coworkers, large-diameter (up to $400\ \text{mm}$) silicon single-crystals with a high degree of perfection that meet state-of-the-art device demands have been grown

by incorporating the Dash technique and successive technological innovations into the apparatus.

Today's research and development efforts concerning silicon crystals are directed toward achieving microscopic uniformity of crystal properties such as the resistivity and the concentrations of impurities and microdefects, as well as microscopic control of them, which will be discussed elsewhere in this Handbook.

Outline of the Process

The three most important steps in CZ crystal growth are shown schematically in Fig. 13.3b. In principle, the process of CZ growth is similar to that of FZ growth: (1) melting polysilicon, (2) seeding and (3) growing. The CZ pulling procedure, however, is more complicated

than that of FZ growth and is distinguished from it by the use of a quartz crucible to contain the molten silicon. Figure 13.6 shows a schematic view of typical modern CZ crystal growth equipment. Important steps in the actual or standard CZ silicon crystal growth sequence are as follows:

1. Polysilicon chunks or grains are placed in a quartz crucible and melted at temperatures higher than the melting point of silicon (1420°C) in an inert ambient gas.
2. The melt is kept at a high temperature for a while in order to ensure complete melting and ejection of tiny bubbles, which may cause voids or negative crystal defects, from the melt.
3. A seed crystal with the desired crystal orientation is dipped into the melt until it begins to melt itself. The seed is then withdrawn from the melt so that the neck is formed by gradually reducing the diameter; this is the most delicate step. During the entire crystal growth process, inert gas (usually argon) flows downward through the pulling chamber in order to carry off reaction products such as SiO and CO.
4. By gradually increasing the crystal diameter, the conical part and shoulder are grown. The diameter is increased up to the target diameter by decreasing the pulling rate and/or the melt temperature.
5. Finally, the cylindrical part of the body with a constant diameter is grown by controlling the pulling rate and the melt temperature while compensating for the drop in the melt level as the crystal grows. The pulling rate is generally reduced toward the tail end of a growing crystal, mainly due to increasing heat radiation from the crucible wall as the melt level drops and exposes more crucible wall to the growing crystal. Near the end of the growth process, but before the crucible is completely drained of molten silicon, the crystal diameter must be gradually reduced to form an end-cone in order to minimize thermal shock, which can cause slip dislocations at the tail end. When the diameter becomes small enough, the crystal can be separated from the melt without the generation of dislocations.

Figure 13.7 shows the seed-end part of an as-grown CZ silicon crystal. Although a seed-corn, which is the transition region from the seed to the cylindrical part, is usually formed to be rather flat for economic reasons, a more tapered shape might be desirable from a crystal quality point of view. The shoulder part and its vicinity should not be used for device fabrication because this part is considered a transition region

Fig. 13.6 Schematic view of typical Czochralski silicon crystal growing system. (After Shimura [13.1])

Fig. 13.7 Seed-end part of as-grown Czochralski silicon crystal

in many senses and it exhibits inhomogeneous crystal characteristics due to the abrupt change in growth conditions.

Figure 13.8 shows an extra-large as-grown CZ silicon crystal ingot 400 mm in diameter and 1800 mm in length grown by the Super Silicon Crystal Research Institute Corporation in Japan [13.2].

Influence of Spatial Location in a Grown Crystal

As Fig. 13.9 clearly depicts, each portion of a CZ crystal is grown at a different time with different growth conditions [13.19]. Thus, it is important to understand that each portion has a different set of crystal characteristics and a different thermal history due to its different position along the crystal length. For example, the seed-end portion has a longer thermal history, ranging from the melting point of 1420°C to around 400°C in a puller, while the tail-end portion has a shorter history and is cooled down rather rapidly from the melting point. Ultimately, each silicon wafer prepared from a different portion of a grown crystal could exhibit different physico-chemical characteristics depending on its location in the ingot. In fact, it has been reported that the oxygen precipitation behavior exhibits the greatest loca-

Fig. 13.8 Extra-large as-grown Czochralski silicon ingot 400 mm in diameter and 1800 mm in length. (Courtesy of Super Silicon Crystal Research Institute Corporation, Japan)

Fig. 13.9 Thermal environment during Czochralski crystal growth at initial and final stages. Arrows indicate approximate directions of heat flow. (After Zulehner and Huber [13.19])

tion dependence, which, in turn, affects the generation of bulk defects [13.20].

Also, a nonuniform distribution of both crystal defects and impurities occurs across the transverse section of a flat wafer prepared from a CZ crystal silicon melt

crystallized or solidified successively at the crystal–melt interface, which is generally curved in the CZ crystal growth process. Such inhomogeneities can be observed as *striations*, which are discussed later.

13.3.3 Impurities in Czochralski Silicon

The properties of the silicon semiconductors used in electronic devices are very sensitive to impurities. Because of this sensitivity, the electrical/electronic properties of silicon can be precisely controlled by adding a small amount of dopant. In addition to this dopant sensitivity, contamination by impurities (particularly transition metals) negatively affects the properties of silicon and results in the serious degradation of device performance. Moreover, oxygen is incorporated at levels of tens of atoms per million into CZ silicon crystals due to the reaction between the silicon melt and the quartz crucible. Regardless of how much oxygen is in the crystal, the characteristics of silicon crystals are greatly affected by the concentration and the behavior of oxygen [13.21]. In addition, carbon is also incorporated into CZ silicon crystals either from polysilicon raw materials or during the growth process, due to the graphite parts used in the CZ pulling equipment. Although the concentration of carbon in commercial CZ silicon crystals is normally less than 0.1 ppma, carbon is an impurity that greatly affects the behavior of oxygen [13.22, 23]. Also, nitrogen-doped CZ silicon crystals [13.24, 25] have recently attracted much attention due to their high microscopic crystal quality, which may meet the requirements for state-of-the-art electronic devices [13.26, 27].

Impurity Inhomogeneity

During crystallization from a melt, various impurities (including dopants) contained in the melt are incorporated into the growing crystal. The impurity concentration of the solid phase generally differs from that of the liquid phase due to a phenomenon known as *segregation*.

Segregation. The equilibrium segregation behavior associated with the solidification of multicomponent systems can be determined from the corresponding phase diagram of a binary system with a *solute* (the impurity) and a *solvent* (the host material) as components.

The ratio of the solubility of impurity A in solid silicon $[C_A]_s$ to that in liquid silicon $[C_A]_L$

$$k_0 = [C_A]_s / [C_A]_L \quad (13.6)$$

is referred to as the *equilibrium segregation coefficient*. The impurity solubility in liquid silicon is always higher than that in solid silicon; that is, $k_0 < 1$.

The equilibrium segregation coefficient k_0 is only applicable to solidification at negligibly slow growth rates. For finite or higher solidification rates, impurity atoms with $k_0 < 1$ are rejected by the advancing solid at a greater rate than they can diffuse into the melt. In the CZ crystal growth process, segregation takes place at the start of solidification at a given seed–melt interface, and the rejected impurity atoms begin to accumulate in the melt layer near the growth interface and diffuse in the direction of the bulk of the melt. In this situation, an *effective segregation coefficient* k_{eff} can be defined at any moment during CZ crystal growth, and the impurity concentration $[C]_s$ in a CZ crystal can be derived by

$$[C]_s = k_{\text{eff}} [C_0] (1 - g)^{k_{\text{eff}} - 1}, \quad (13.7)$$

where $[C_0]$ is the initial impurity concentration in the melt and g is the fraction solidified.

Consequently, it is clear that a macroscopic longitudinal variation in the impurity level, which causes a variation in resistivity due to the variation in the dopant concentration, is inherent to the CZ batch growth process; this is due to the segregation phenomenon. Moreover, the longitudinal distribution of impurities is influenced by changes in the magnitude and the nature of melt convection that occur as the melt aspect ratio is decreased during crystal growth.

Striations. In most crystal growth processes, there are transients in the parameters such as instantaneous microscopic growth rate and the diffusion boundary layer thickness which result in variations in the effective segregation coefficient k_{eff} . These variations give rise to microscopic compositional inhomogeneities in the form of *striations* parallel to the crystal–melt interface. Striations can be easily delineated with several techniques, such as preferential chemical etching and X-ray topography. Figure 13.10 shows the striations revealed by chemical etching in the shoulder part of a longitudinal cross-section of a CZ silicon crystal. The gradual change in the shape of the growth interface is also clearly observed.

Striations are physically caused by the segregation of impurities and also point defects; however, the striations are practically caused by temperature fluctuations near the crystal–melt interface, induced by unstable thermal convection in the melt and crystal rotation in an asymmetric thermal environment. In addition, mechanical vibrations due to poor pulling control mechanisms

Fig. 13.10 Growth striations, revealed by chemical etching, in a shoulder of Czoehrski silicon

in the growth equipment can also cause temperature fluctuations.

Figure 13.11 schematically illustrates a CZ-grown crystal cross-section containing a curved crystal–melt interface, which results in inhomogeneities on the surface of a slice. As each planar wafer is sliced, it contains different portions of several curved striations. Different “phonograph rings”, referred to as *swirl*, can then occur in each wafer, which can be observed across the wafer using the techniques mentioned above.

Doping

In order to obtain the desired resistivity, a certain amount of dopant (either donor or acceptor atoms) is added to a silicon melt according to the resistivity–concentration relation. It is common practice to add dopants in the form of highly doped silicon particles or chunks of about $0.01\ \Omega\text{ cm}$ resistivity, which are called the dopant fixture, since the amount of pure dopant needed is unmanageably small, except for heavily doped silicon materials (n^+ or p^+ silicon).

The criteria for selecting a dopant for a semiconductor material are that it has the following properties; (1) suitable energy levels, (2) high solubility, (3) suitable or low diffusivity, and (4) low vapor pressure. A high diffusivity or high vapor pressure leads to undesirable diffusion or vaporization of dopants, which results in unstable device operation and difficulties in achieving precise resistivity control. A solubility that is too small limits the resistivity that can be obtained. In addition to

Fig. 13.11 Schematic illustration of Czoehrski crystal cross-section containing a curved crystal–melt interface and planar wafers sliced into different portions. (After Shimura [13.1])

those criteria, the chemical properties (the toxicity for example) must be considered. A further consideration from the viewpoint of crystal growth is that the dopant has a segregation coefficient that is close to unity in order to make the resistivity as uniform as possible from the seed-end to the tail-end of the CZ crystal ingot. Consequently, phosphorus (P) and boron (B) are the most commonly used donor and acceptor dopants for silicon, respectively. For n^+ silicon, in which donor atoms are heavily doped, antimony (Sb) is usually used instead of phosphorus because of its smaller diffusivity, in spite of its small segregation coefficient and high vapor pressure, which lead to large variations in concentration in both the axial and the radial directions.

Oxygen and Carbon

As shown schematically in Figs. 13.3b and 13.6, a quartz (SiO_2) crucible and graphite heating elements are used in the CZ-Si crystal growth method. The surface of the crucible that contacts the silicon melt is gradually dissolved due to the reaction

This reaction enriches the silicon melt with oxygen. Most of the oxygen atoms evaporate from the melt surface as volatile silicon mono-oxide (SiO), but some of them are incorporated into a silicon crystal through the crystal–melt interface.

However, the carbon in CZ silicon crystals originates mainly from the polycrystalline starting material. Levels

Fig. 13.12 Incorporation of oxygen and carbon into Czochralski silicon crystal. (After Shimura [13.1])

of carbon ranging from 0.1 to 1 ppma, depending on the manufacturer, are found in the polysilicon. Sources of carbon in polysilicon are assumed to be mainly carbon-containing impurities found in the trichlorosilane used in the production of polysilicon. Graphite parts in CZ pulling equipment can also contribute to carbon contamination by reacting with oxygen, which is always present during the ambient growth. The resulting products of CO and CO₂ are dissolved into the silicon melt and account for the carbon impurities in silicon crystals. Thus, oxygen and carbon are the two major nondoping impurities that are incorporated into CZ silicon crystals in the way shown schematically in Fig. 13.12. The behavior of these impurities in silicon, which affect a number of the properties of CZ silicon crystals, has been the subject of intensive study since the late 1950s [13.21].

13.4 New Crystal Growth Methods

Silicon crystals used for microelectronic device fabrication must meet a variety of requirements set by device manufacturers. In addition to the requirements for silicon wafers, the following crystallographic demands have become more common due to high-yield and high-performance microelectronic device manufacturing.

1. large diameter
2. low or controlled defect density
3. uniform and low radial resistivity gradient
4. optimum initial oxygen concentration and its precipitation.

It is clear that silicon crystal manufacturers must not only meet the above requirements but also produce those crystals economically and with high manufacturing yields. The main concerns of silicon crystal growers are the crystallographic perfection and the axial distribution of dopants in CZ silicon. In order to overcome some problems with the conventional CZ crystal growth method, several new crystal growth methods have been developed.

13.4.1 Czochralski Growth with an Applied Magnetic Field (MCZ)

The melt convection flow in the crucible strongly affects the crystal quality of CZ silicon. In particular, unfav-

orable growth striations are induced by unsteady melt convection resulting in temperature fluctuations at the growth interface. The ability of a magnetic field to inhibit thermal convection in electrically conducting fluid was first applied to the crystal growth of indium antimonide via the horizontal boat technique [13.28] and the horizontal zone-melting technique [13.29]. Through these investigations, it was confirmed that a magnetic field of sufficient strength can suppress the temperature fluctuations that accompany melt convection, and can dramatically reduce growth striations.

The effect of the magnetic field on growth striations is explained by its ability to decrease the turbulent thermal convection of a melt and in turn decrease the temperature fluctuations at the crystal–melt interface. The fluid flow damping caused by the magnetic field is due to the induced magnetomotive force when the flow is orthogonal to the magnetic flux lines, which results in an increase in the effective kinematic viscosity of the conducting melt.

Silicon crystal growth by the magnetic field applied CZ (MCZ) method was reported for the first time in 1980 [13.30]. Originally MCZ was intended for the growth of CZ silicon crystals that contain low oxygen concentrations and therefore have high resistivities with low radial variations. In other words, MCZ silicon was expected to replace the FZ silicon almost exclusively

used for power device fabrication. Since then, various magnetic field configurations, in terms of the magnetic field direction (horizontal or vertical) and the type of magnets used (normal conductive or superconductive), have been developed [13.31]. MCZ silicon produced with a wide range of desired oxygen concentrations (from low to high) has been of great interest for different device applications. The value of MCZ silicon lies in its high quality and its ability to control the oxygen concentration over a wide range, which cannot be achieved using the conventional CZ method [13.32], as well as its enhanced growth rate [13.33].

As far as the crystal quality is concerned, there is no doubt that the MCZ method provides the silicon crystals most favorable to the semiconductor device industry. The production cost of MCZ silicon may be higher than that of conventional CZ silicon because the MCZ method consumes more electrical power and requires additional equipment and operating space for the electromagnets; however, taking into account the higher growth rate of MCZ, and when superconductive magnets that need smaller space and consume less electrical power compared with conductive magnets are used, the production cost of MCZ silicon crystals may become comparable to that of conventional CZ silicon crystals. In addition, the improved crystal quality of MCZ silicon may increase production yields and lower the production cost.

13.4.2 Continuous Czochralski Method (CCZ)

Crystal production costs depend to a large extent on the cost of materials, in particular the cost of those used for quartz crucibles. In the conventional CZ process, called a *batch process*, a crystal is pulled from a single crucible charge, and the quartz crucible is used only once and is then discarded. This is because the small amount of remaining silicon cracks the crucible as it cools from a high temperature during each growth run.

One strategy for replenishing a quartz crucible with melt economically is to continuously add feed as the crystal is grown and thereby maintain the melt at a constant volume. In addition to saving crucible costs, the continuous-charging Czochralski (CCZ) method provides an ideal environment for silicon crystal growth. As already mentioned, many of the inhomogeneities in crystals grown by the conventional CZ batch process are a direct result of the unsteady kinetics arising from the change in melt volume during crystal growth. The CCZ method aims not only to reduce production costs but also to grow crystals under steady conditions. By maintain-

Fig. 13.13 Schematic illustration of the continuous-charging Czochralski method. (After Zulehner [13.34])

ing the melt volume at a constant level, steady thermal and melt flow conditions can be achieved (see Fig. 13.9, which shows the change in thermal environments during conventional CZ growth).

Continuous charging is commonly performed by polysilicon feeding, as shown in Fig. 13.13 [13.34]. This system consists of a hopper for storing the polysilicon raw material and a vibratory feeder that transfers the polysilicon to the crucible. In the crucible that contains the silicon melt, a quartz baffle is required to prevent the melt turbulence caused by feeding in the solid material around the growth interface. Free-flowing polysilicon granules such as those mentioned previously are obviously advantageous for the CCZ method.

The CCZ method certainly solves most of the problems related to inhomogeneities in crystal grown by the conventional CZ method. Moreover, the combination of MCZ and CCZ (the magnetic-field-applied continuous CZ (MCCZ) method) is expected to provide the ultimate crystal growth method, giving ideal silicon crystals for a wide variety of microelectronic applications [13.1]. Indeed, it has been used to grow high-quality silicon crystals intended for microelectronic devices [13.35].

However, it should be emphasized that the different thermal histories of different parts of the crystal (from the seed to the tail ends, as shown in Fig. 13.9) must be considered even when the crystal is grown by the ideal growth method. In order to homogenize the grown crystal or to obtain axial uniformity in the thermal history, some form of post-treatment, such as high-temperature annealing [13.36], is required for the crystal.

Fig. 13.14 200 mm-diameter dislocation-free Czochralski silicon crystal grown without the Dash necking process. (Courtesy of Prof. K. Hoshikawa)

13.4.3 Neckingless Growth Method

As mentioned previously, Dash's necking process (which grows a thin neck 3–5 mm in diameter, Fig. 13.7) is a critical step during CZ crystal growth because it eliminates grown-in dislocations. This technique has been the industry standard for more than 40 years. However, recent demands for large crystal diameters (> 300 mm, weighing over 300 kg) have resulted in the need for larger diameter necks that do not introduce dislocations into the growing crystal, since a thin neck 3–5 mm in diameter can not support such large crystals.

Large diameter seeds that are typically 170 mm long, with a minimum diameter of > 10 mm and

an average of 12 mm grown from silicon melt heavily doped with boron ($> 10^{19}$ atoms/cm³) have been used to grow dislocation-free 200 mm-diameter CZ silicon crystals [13.37, 38]. It is estimated that large diameter necks 12 mm in diameter can CZ support crystals as heavy as 2000 kg [13.39]. Figure 13.14a shows a 200 mm-diameter dislocation-free CZ silicon crystal grown without the Dash necking process, and Fig. 13.14b shows its enlarged seed (compare with Fig. 13.7). The mechanism by which dislocations are not incorporated into the growing crystal has been primarily attributed to hardening effect of the heavy doping of boron in the silicon.

14. Epitaxial Crystal Growth: Methods and Materials

The epitaxial growth of thin films of material for a wide range of applications in electronics and optoelectronics is a critical activity in many industries. The original growth technique used, in most instances, was liquid-phase epitaxy (LPE), as this was the simplest and often the cheapest route to producing device-quality layers. These days, while some production processes are still based on LPE, most research into and (increasingly) much of the production of electronic and optoelectronic devices now centers on metalorganic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE). These techniques are more versatile than LPE (although the equipment is more expensive), and they can readily produce multilayer structures with atomic-layer control, which has become more and more important in the type of nanoscale engineering used to produce device structures in as-grown multilayers. This chapter covers these three basic techniques, including some of their more common variants, and outlines the relative advantages and disadvantages of each. Some examples of growth in various important systems are also outlined for each of the three techniques.

This chapter outlines the three major epitaxial growth processes used to produce layers of material for electronic, optical and optoelectronic applications. These are liquid-phase epitaxy (LPE), metalorganic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE).

We will also consider their main variants. All three techniques have advantages and disadvantages when applied to particular systems, and these will be highlighted where appropriate in the following sections.

14.1 Liquid-Phase Epitaxy (LPE)

14.1.1 Introduction and Background

Liquid-phase epitaxy (LPE) is a mature technology and has unique features that mean that it is still applicable for use in niche applications within certain device technolo-

gies. It has given way in many areas, however, to various vapor-phase epitaxy techniques, such as metalorganic vapor phase, molecular beam and atomic layer epitaxies (MOVPE, MBE, ALE), see Sects. 14.2 and 14.3. When selecting an epitaxial growth technology for a par-

ticular material system and/or device application, the choice needs to take into account the basic principles of thermodynamics, kinetics, surface energies, and so on, as well as practical issues of reproducibility, scalability, process control, instrumentation, safety and capital equipment costs. A systematic comparison of the various epitaxy techniques suggests that no single technique can best satisfy the needs of all of the material/device combinations needed in microelectronics, optoelectronics, solar cells, thermophotovoltaics, thermoelectrics, semiconductor electrochemical devices, magnetic devices and microelectromechanical systems. LPE is still a good choice for many of these application areas (M. Mauk, private communication, 2004).

14.1.2 History and Status

LPE is basically a high-temperature solution growth technique [14.1] in which a thin layer of the required material is deposited onto a suitable substrate. Homoepitaxy is defined as growth of a layer of the same composition as the substrate, whereas heteroepitaxy is the growth of a layer of markedly different composition. A suitable substrate material would have the same crystal structure as the layer, have as close a match in terms of lattice parameters as possible and be chemically compatible with the solution and the layer. Nelson [14.2] is commonly thought to have developed the first LPE systems, in this case for producing multilayer compound semiconducting structures. In the following decades a large technology base was established for III–V compound semiconductor lasers, LEDs, photodiodes and solar cells. LPE has been applied to the growth of Si, Ge, SiGe alloys, SiC, GaAs, InP, GaP, GaSb, InAs, InSb (and their ternary and quaternary alloys), GaN, ZnSe, CdHgTe, HgZnTe and HgMnTe. It has also been used to produce a diverse range of oxide/fluoride compounds, such as high-temperature superconductors, garnets, para- and ferroelectrics and for various other crystals for optics and magnetics. The early promise of garnet materials for making ‘bubble’ memories was not fully realised as standard semiconductor memory was more commercially viable. Dipping LPE is still used to make magneto-optical isolators by epitaxially growing garnet layers on gadolinium gallium garnet substrates.

It is probably true to say that most of these systems were first studied using LPE, where it was used in the demonstration, development and commercialization of many device types, including GaAs solar cells, III–V LEDs and laser diodes, GaAs-based Gunn-effect and other microwave devices and various IR detectors based

on InSb and on CdHgTe. Nevertheless, LPE does not appear in the research literature as often as, say, MOVPE, MBE and ALE in reference to work in these systems. However, it is still used extensively in industrial applications, including III–V LEDs, particularly those based on AlGaAs and GaP alloys, where it is ideally suited to the small die areas, the high luminescence efficiencies and the relatively simple device structures needed, and IR detectors based on CdHgTe.

Realistic industrial production data is difficult to obtain, but Moon [14.3] noted that the large majority of optoelectronic devices were still being grown by LPE at that time, amounting to $\approx 4000 \text{ m}^2$ per year. He also estimated that despite the loss of market share to more advanced techniques, the total demand for LPE material was still increasing at $\approx 10\%$ per year. LPE was discontinued for many applications because of its perceived limitations in regard to control of layer thickness, alloy compositions, doping, interface smoothness and difficulties in growing certain combinations of interest for heterostructure devices. LPE is normally dismissed for the production of superlattices, quantum wells, strained-layer structures and heterojunctions with large lattice mismatches of chemical dissimilarities. It also suffers from a reputation for poor reproducibility, problems with scaling up in size or throughput, and difficulties in achieving abrupt interfaces between successive layers within structures.

14.1.3 Characteristics

LPE is characterized as a near-equilibrium growth process, when compared to the various vapor-phase epitaxy techniques. Heat and mass transport, surface energies, interface kinetics and growth mechanisms are different in LPE compared to those in vapor-phase epitaxy or bulk growth techniques. These features result in both advantages and disadvantages for LPE. The former include:

- High growth rates. These are typically $0.1\text{--}10 \mu\text{m/h}$, i. e. faster than in MOVPE or MBE. This feature is useful when thick layers or “virtual substrates” are required.
- Favorable segregation of impurities into the liquid phase. This can lead to lower residual or background impurities in the epitaxial layer.
- Ability to produce very flat surfaces and excellent structural perfection (Fig. 14.1).
- Wide selection of dopants. Most solid or liquid elements can be added to a melt and incorpo-

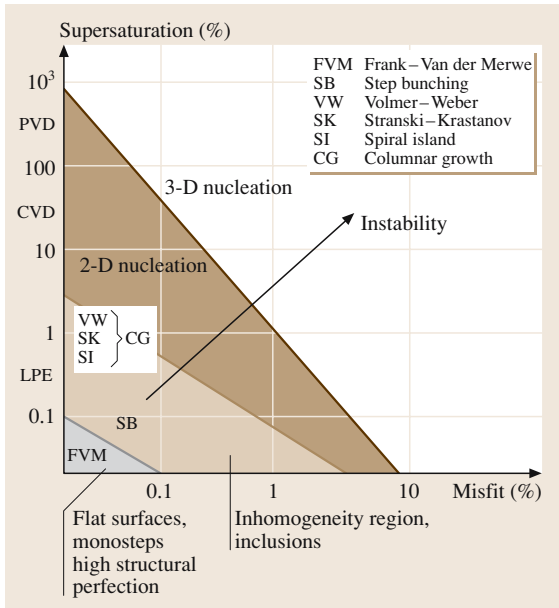

Fig. 14.1 The effects of both supersaturation (and the growth method) and misfit on the nucleation and growth regimes. Only at very low supersaturation in LPE using low-misfit substrates can really flat surfaces be expected. (After [14.4])

rated in the layer, unlike in vapor-phase growth where the development of volatile dopant precursors with suitable kinetics and sticking coefficients is a major undertaking. In this regard, there is work underway on rare-earth doping of semiconductor layers to exploit their gettering and optical properties.

- Suppression of certain types of defects. In general, LPE material has lower point defects (vacancies, interstitials, antisites) than material made by other techniques. For example, the Ga-rich conditions during GaAs LPE inhibits the formation of the As

antisite defect that is responsible for the nonradiative losses in luminescent devices.

- Once the relevant phase diagram is established, growth can be made to occur over a wide range of temperatures.
- Absence of highly toxic precursors or byproducts.
- Low capital equipment and operating costs. A research LPE kit can be constructed for under \$50 000.

The main consideration when designing an LPE process is to determine accurate phase equilibria (S–L and/or S–L–V) of the required system. Solution modeling, extrapolations of existing phase equilibria and semi-empirical predictions are usually sufficient to guide developments in new systems/applications. The near-equilibrium nature of LPE provides for several important growth modes, such as selective epitaxy (deposition through masks on a substrate) and epitaxial layer overgrowth (ELOG, where growth over a mask occurs), which are useful for defect reduction and new device structures. These new areas include work on the currently important growth of SiC and GaN for diode applications.

14.1.4 Apparatus and Techniques

The basic requirement is to bring the substrate and growth solution into contact while the epitaxial layer grows, and then to separate them cleanly at the end of the growth cycle. The three main embodiments of the LPE growth method are tipping, dipping and sliding boat, see Fig. 14.2.

Figure 14.3 shows the tipping furnace system used by Nelson [14.2]. The boat, normally graphite or silica, sits in the work tube in the center of the tilted furnace such that the substrate, held with a clamp, is held at one end of the boat with the growth solution at the other end. Once the melt has been equilibrated the temperature is

Fig. 14.2 Dipping, sliding boat and tipping LPE arrangements. (After [14.5])

Fig. 14.4 Schematic diagram of a dipping LPE reactor showing the Te-rich melt, the mercury reservoir and positions of the sensors. (After [14.5])

Fig. 14.5 Basic structure of graphite horizontal sliding-boat LPE. (After [14.6])

slowly reduced and the furnace is tipped to roll the solution over the substrate. After a suitable time the furnace is tipped back to the start position and the solution rolls off the grown layer. This is a relatively simple and cheap technique but has the limitations that solution removal is difficult and it is normally only suitable for single-layer growth.

Figure 14.4 shows the dipping system used for the growth of CdHgTe [14.5]. The design and operation of a system for growth from Hg-rich melts is dominated by consideration of the high vapor pressure of Hg that comprises $\geq 90\%$ of the growth solution, which led to the evolution of a vertical high-pressure furnace design with a cooled reflux region. The cylindrical melt vessel consists of a high-strength stainless steel chamber lined with quartz. Such systems are capable of containing about 10–20 kg of melt at 550 °C for several years with no degradation in melt integrity or purity. The prepared substrates are introduced into the melt through a transfer chamber or air lock. The paddle assembly can be lowered into the melt and rotated to stir the melt. In general, the high-purity melt components are introduced into the clean melt vessel at room temperature. The system is sealed, evacuated and pressurized. The temperature of the furnace is raised above the predicted melting point and held constant until all the solute dissolves. The use of large melts results in a near-constant saturation temperature from run to run and ensures excellent reproducibility of layer characteristics.

Figure 14.5 shows the basic structure of a graphite sliding-boat system, which has turned out to be the most popular and versatile of the three main methods [14.6]. The substrate sits in a recess in a slider supported by a base section. Growth solutions reside in wells in the upper section of the boat and can be repositioned over the substrate using a push-rod arrangement. One of the main drawbacks of this method is that of melt retention on the grown layer. Various means, such as empty wells, slots, lids on the solutions, and pistons to tilt the substrate have been tried with varying degrees of success. The critical design feature of the boat to aid wipe-off is to control the gap between the top of the grown layer and the underside of the top section. If this is too large, melt retention occurs, but if it is too small the layer may be scratched. Multilayer growth is easily possible using this sliding-boat method, providing melt retention is kept to a minimum. The thin melts lead to suppression of thermal or solutal convection, and hence reduce enhanced edge growth. Scale-up has also been achieved in this method with several substrates (up to 16) growing three-layer GaAlAs structures in a single run.

In all of the LPE methods, production of supersaturation in the growth solution drives the deposition of the layer on the substrate. This supersaturation can be produced by ramp cooling, step cooling, supercooled growth (a hybrid of the previous two techniques), two-phase growth, constant-temperature growth or transient growth [14.7]. The choice between these various means will depend on the details of the particular material system and the precise requirement for the material. An additional means of producing the required supersaturation is that of electroepitaxy, in which an electric current is passed through the interface to stimulate layer growth. It is now thought that this occurs via an electromigration process rather than via Peltier cooling. Benefits claimed for the technique include reduced surface ripple, a reduced number of certain microdefects and an ability to grow millimeter-thick layers of GaAlAs with uniform composition.

14.1.5 Group IV

Silicon and Silicon/Germanium

Ciszek [14.9] noted that high-quality Si layers have been grown on Si substrates at temperatures in the range 700–900 °C at a rate of 1 $\mu\text{m}/\text{min}$. The potential application was for solar cells, but because growth was on silicon, rather than a low-cost alternative, this is not considered to be a viable production process.

Alonso and Winer [14.10] grew SiGe alloys of various compositions from Si–Ge–In melts at temperatures between 640 and 900 °C. Layers were 1–5 μm thick and were used to study Raman spectra features seen in material grown by MBE. The advantage of LPE-grown material was thought to lie in the random distribution of Si and Ge atoms (no ordering is present) compared to the MBE-grown material. The authors were able to show that the Raman peaks seen in MBE-grown material were not due to ordering; rather they were due to optical phonons associated with Si–Si motion. This demonstrates the benefits that a near-equilibrium growth process can have when studying material grown by ‘nonequilibrium’ techniques.

Silicon Carbide

Dmitriev [14.8, 11] has described the production of high-quality 6H-SiC and 4H-SiC p-n junctions by LPE from Si melts. Layer thicknesses range from 0.2 to 100 μm with growth rates of 0.01–2 $\mu\text{m}/\text{min}$. Nitrogen is used as the donor impurity and aluminium, gallium and boron as acceptor impurity elements. The material showed high carrier mobility and low deep-center concentrations. Ini-

tial attempts used a technique where molten silicon ran from an upper section of the crucible to a lower section where the SiC substrates were held fixed. Dipping was also used in an attempt to grow material that was less stressed by Si melt solidification. Growth temperatures were 1500–1750 °C and layer thicknesses were 20–40 μm . Both of these techniques produced material that was successfully used to make blue LEDs. A new version of LPE, so-called container-free LPE (CFLPE) based on the electromagnetic crucible technique, was also developed, see Fig. 14.6. Liquid metal (molten Si) is suspended in a high-frequency electromagnetic field at 1000 °C and the substrates, SiC, are placed on top of the melt after heating to 1450 °C. A source of SiC is also placed at the bottom of the Si melt. Cooling of the solution was used to produce the epitaxial layer and the

Fig. 14.6a–d Schematic of CFLPE: 1 – silicon, 2 – inductor, 3 – SiC substrate, 4 – copper container; (a) solid Si in copper inductor, (b) solid Si suspended in the inductor, (c) liquid Si with SiC crystals suspended in the electromagnetic field, (d) Si is dropped into the container. (After [14.8])

samples were then removed from the melt. The technique succeeded in producing p–n junctions by growing both layers in the same run. These formed the basis of several types of high-temperature devices (up to 500 °C), including diodes, FETs, bipolar transistors and dynistors, and optoelectronic devices such as green, blue, violet and UV LEDs. Reductions in melt temperature have been attempted by adding Sn, Ge and Ga to Si melts, with some success being reported for the latter; growth at 1100–1200 °C was obtained.

14.1.6 Group III–V

Arsenic- and Phosphorus-Based Materials

The majority of work in the area of III–V growth has been on GaAs and GaP, plus additions of As and Al. Following the earlier treatment by *Elwell* and *Scheel* [14.1], *Astles* [14.7] gave a comprehensive treatment of the LPE growth of GaAs and other III–V binaries and ternaries. He lists the advantages of LPE as: high luminescence efficiency due to the low concentration of nonradiative centers and deep levels, growth of ternary and quaternary alloys, controlled p- and n-type doping, multilayer growth with low interface recombination velocities and good reproducibility and uniformity. Disadvantages included: large areas that are required to be free of surface features (such as for photocathodes or ICs), very abrupt control of doping/composition profiles is required (as for microwave devices), accurate thickness control is required (as for microwave and quantum-well devices), and compositional grading between the substrate and the layer is inevitable. A problem associated with the use of phosphorus-containing substrates is the need to provide an overpressure source or a dummy solution to prevent phosphorus loss during the pregrowth phases.

All of the methods outlined above were attempted for the growth of GaAs and related materials. In addition, because LPE is a near-equilibrium technique that uses low supersaturation, nucleation is very sensitive to substrate lattice parameters and the growth rate is influenced by the substrate orientation. This enables localized growth in windows on the substrate surface and growth on nonplanar substrates with ribs or channels produced by preferential etching. The latter feature has been used to produce novel laser structures.

In fact, a vast array of both optoelectronic and microwave devices have been produced in LPE GaAs and related materials. The earliest were the GaAs Gunn devices and GaP/GaAsP LEDs. Later, GaAs/GaAlAs heterojunctions were produced for use in lasers, photocathodes and solar cells. Other alloy systems, such as

GaInP for blue/green LEDs, GaInSb for improved Gunn devices, and GaInAs or GaAsSb for photocathodes were also studied. Later still came growth of ternaries, such as GaInAsP (lattice-matched to InP) for heterostructure optoelectronic devices. Finally, OEICs and buried heterostructure lasers were developed to exploit the potential for selective-area growth and anisotropy of growth rate.

III–V Antimonides

Commercially available substrates for epitaxy are limited in their lattice constant spread and this imposes certain constraints in terms of lattice-matched growth and miscibility gaps. Ternary and quaternary alloy substrates with adjustable lattice parameters would open up new device applications. However, bulk-grown ternary alloys suffer from segregation and stress effects. An alternative approach is to grow very thick layers (> 50 µm) of these compounds for use as ‘virtual substrates’, *Mao* and *Krier* [14.12]. For III–V antimonides, where substrate and lattice-matching problems are acute, such thick layers are feasible by LPE due to the relatively fast growth rates (1–10 µm/min). Either gradual compositional grading or growing multilayers with abrupt but incremental compositional changes between layers can be combined with either selective removal of the substrate (to produce free-standing layers) or wafer-bonding techniques, yielding an alloy layer bonded to a surrogate substrate. The challenge for these virtual substrates is to produce lattice constants that are sufficiently different from those available using binary substrates, without introducing an excessive level of defects.

Another interesting application of antimonides is that of InSb-based quantum dots, *Krier* et al. [14.13]. The potential application here is in mid-IR lasers, LEDs and detectors. In particular, there is a market for these materials as gas detectors based on IR absorption. The principle is that of rapid slider LPE, in which a thin slit of melt is wiped across the substrate producing contact times of 0.5–200 ms. This produces low-dimensional structures such as quantum wells and quantum dots. InSb quantum dots were grown on InAs substrates at 465 °C with 10 °C supercooling and a 1 ms melt–substrate contact time. Both small (4 nm high and 20 nm in diameter) and large quantum dots (12 nm high and 60 nm in diameter) are produced. Extensions to this work included growing InSb dots on GaAs and InAsSb dots. Photoluminescence and electroluminescence in the mid-IR region ($\approx 4 \mu\text{m}$) were observed in these dots.

A Japanese group [14.14] is pioneering a technique called melt epitaxy, which can be viewed as a variant

of LPE. A sliding-boat arrangement rapidly solidifies a ternary melt into a $\approx 300\text{ }\mu\text{m}$ -thick ternary slab on a binary substrate. For example, thick InGaSb and InAsSb layers were grown onto GaAs and InAs substrates, respectively. Low background doping and high electron mobilities are achieved in material that demonstrates cut-off wavelengths in the 8–12 μm region, potentially a competitor to the more established IR detectors based on MCT (Sect. 14.1.7).

Group III Nitrides

The LPE of GaN is difficult due to the low solubility of nitrogen in molten metals at atmospheric pressure. There are reports of growth of GaN from gallium and bismuth melts, and in some instances the melt is replenished with nitrogen by introducing ammonia into the growth ambient, relying on a so-called VLS (vapor-liquid-solid) growth mechanism that essentially combines LPE with CVD (chemical vapor deposition). Another report [14.15] notes the use of Na fluxes as a solvent. *Klemenz* and *Scheel* [14.16] used a dipping mode at 900 °C with sapphire, LiGaO₂, LiAlO₂ and CVD GaN on sapphire substrates.

Other Topics

Doping with rare-earth elements (Dy, Er, Hf, Nd, Pr, Yb, Y, ...) in the AlGaAs, InGaAs, InGaAsSb and InGaAsP systems can lead to impurity gettering effects that radically reduce background doping and junction saturation currents and increase carrier mobilities and minority carrier lifetimes. Such rare-earth doping in InAsSb LEDs [14.17] increases the luminescence by 10–100 times.

There is no fundamental limit to the number of components in mixed alloy layers produced by LPE. For example, AlGaInPAs layers have been grown on GaAs by LPE [14.18]. Each additional element adds an extra degree of freedom for tailoring the properties of the layer, although more detailed phase equilibria data or models are required to determine accurate melt compositions and temperatures. However, as more constituents are added the melt becomes more dilute and more nearly approaches ideal behavior.

Traditionally, LPE melts are rich in one of the major components of the layer to be grown. However, there are certain advantages to using alternative solvents, such as bismuth, as used for GaAs. In the latter case the melt is then dilute in both arsenic and gallium and the chemical activities can be separately controlled to try to reduce point defects since the concentrations of these defects depend on the chemical potentials of the constituents.

Bismuth also has lower surface tension that provides better wetting of the substrate. Solubilities can also be changed to affect growth rates or segregation of certain elements, such as Al in AlGaAs. Other solvents that might be considered include molten salts, alloys with Hg, Cd, Sb, Se, S, Au, Ag, or even perhaps some fused oxides.

Several groups have reported success with LPE growth of several less-common semiconductors, such as InTlAsSb, InBiSb and GaMnAs [14.14]. The drive for this work is for low-bandgap material for use in detectors to rival those made in MCT (Sect. 14.1.7).

The low supersaturation of LPE makes selective modes of epitaxy feasible. A substrate can be masked (using, say, SiO₂, Si₃N₄, TiN) and patterned with openings that serve as sites for preferential nucleation. In epitaxial lateral overgrowth (ELO), the selectively seeded material overgrows the mask. This technique has been used for defect filtering, stress reduction, substrate isolation and buried mirrors and electrodes [14.14]. ELO is difficult with vapor-phase methods; aspect ratios (width to thickness of selectively grown material) are small, whereas they can be 100 in LPE. This could have potential for light-emitting diodes [14.14]. Another interesting application of selective LPE is the growth of pyramidal AlGaAs microtips for scanning near-field optical microscopy.

LPE growth of heterostructures with high lattice mismatch has also been attempted, for example of InSb on GaAs [14.14] and AlGaAs on GaP [14.14]. This can be assisted by growing a buffer layer by CVD, as in the LPE of AlGaAs on GaAs-coated (by MOCVD or MBE) silicon substrates. Defect-density reductions of ≈ 2 orders of magnitude can be achieved relative to the GaAs buffer layer grown by MOCVD or MBE.

Another variant of the basic LPE process is that of liquid-phase electroepitaxy (LPEE), where application of an electric current through the growth interface can enhance growth rates for producing thick ternary layers [14.14]. Selective LPEE on patterned, tungsten-masked GaAs substrates can produce inverted pyramid-shaped crystals that can be used to make very high efficiency LEDs [14.14].

Mauk et al. [14.19] have reported on a massive scaling up of the LPE growth of thick ($> 50\text{ }\mu\text{m}$) AlGaAs on 75 mm-diameter GaAs substrates. The method produces a two orders of magnitude improvement in areal throughput compared to conventional horizontal sliding boat systems and has applications for LEDs, thermophotovoltaic devices, solar cells and detectors. A large rectangular aluminium chamber is used instead

Fig. 14.7a,b Schematic of three-inch LPE apparatus, (a) perspective view, (b) side view. (After [14.19])

of a silica tube (Fig. 14.7). A modified sliding-boat arrangement is used with a top heater mounted above the boat cap, in conjunction with a heat exchanger/pedestal that acts as a cold finger to impose a vertical temperature gradient, which is the driving force for growth. These $> 50 \mu\text{m}$ -thick layers were then produced as free-standing layers bonded to glass.

14.1.7 Group II–VI

Widegap Compounds

While vapor-phase methods are normally used, LPE has been used to grow some widegap Zn-based II–VI compounds [14.20]. This work was driven by the view at that time that blue LEDs could be made economically in ZnSe. The aim was to produce p–n junctions directly by LPE via growth at $950\text{--}650^\circ\text{C}$, much lower than the bulk crystal growth, to reduce the number of defects. The problems included the high Se vapor pres-

sure, necessitating a closed-tube approach, and the need to maintain the ZnSe substrates in the upper portion of the vertically held melt during deposition. Nevertheless, $10\text{--}20 \mu\text{m}$ -thick layers were grown in 2 h. Growth at 950°C produced smoother surfaces, but the layers contained more deep levels and impurities compared with those grown at the lower temperatures. Addition of a separate Zn vapor pressure source improved the properties, showing p-type conductivity, and doping with Au, Na, and Li was also attempted. All of these produced p-type material but there was no n-type material reported. More recently, the same group [14.21] reported growth of p-type ZnSe doped with Na_2Se from which p–n junctions were fabricated after Ga diffusion from a Zn solution, to produce the n-type layer. Blue light was emitted at a wavelength of 471 nm .

Astles [14.22] has reviewed the work done on LPE of CdTe-based compounds. Most studies have been carried out from Te-rich solutions in the temperature range $500\text{--}900^\circ\text{C}$. Layers are p-type as-grown or n-type if doped with In or Al. Growth rates are typically $0.5 \mu\text{m}/^\circ\text{C}$ at 500°C . Growth from Bi-rich melts was also studied and this was found to improve melt wipe-off and surface morphology. Buffer layer growth of CdZnTe layers was used by Pellicciari et al. [14.23] as impurity barrier layers. Both CdMnTe [14.24] and HgCdMnTe [14.25] have also been grown by LPE. The latter compound was used to produce mesa diodes for room-temperature $1.3\text{--}1.8 \mu\text{m}$ applications.

Mercury Cadmium Telluride (MCT)

The situation regarding LPE of MCT was reviewed by Capper et al. [14.5]. LPE has emerged as the predominant materials growth technology for the fabrication of both first- and second-generation MCT IR focal plane arrays (FPAs). The technology has advanced to the point where material can now be routinely grown for high-performance photoconductive (PC), photovoltaic (PV) and laser detector devices covering the entire $2\text{--}18 \mu\text{m}$ spectral region. Two different technical approaches have been pursued with almost equal success: growth from Hg solutions and growth from Te solutions. One major advantage of the Hg-solution technology is its ability to produce layers of excellent surface morphology due to the ease of melt decanting. Two additional unique characteristics have now been widely recognized as essential for the fabrication of high-performance double-layer heterojunction (DLHJ) detectors by LPE: low liquidus temperature ($< 400^\circ\text{C}$), which makes a cap-layer growth step feasible, and ease of incorporating both

p-type and n-type temperature-stable impurity dopants, such as As, Sb and In, during growth.

Figure 14.4 shows the dipping system used for the growth of CdHgTe [14.5]. A typical growth procedure begins by lowering the paddle plus substrates into the melt and allowing thermal equilibrium to be reached while stirring. After reaching equilibrium, a programmed ramp reduces the melt temperature to the required level at which point the shutters are opened and the substrates are exposed to the melt. Upon completion, the paddle is withdrawn into the transfer chamber and the isolation valve is closed. Large melts allow the production of layers of up to 30 cm² with excellent compositional and thickness uniformity and allow dopant impurities to be accurately weighed for incorporation into layers and to maintain stable electrical characteristics over a long period of time. Four layers (30 cm² each) with a total area of 120 cm² can be grown in a single run [14.27]. Norton et al. [14.28] also scaled up for the growth of cap layers from Hg-rich solutions, each reactor capable of growth on four 24 cm² base layers per run.

While layers grown from Hg-rich solutions are easily doped with group VB elements with high solubility, layers grown from tellurium-rich solutions are not. Group VB dopants have low solubility and are not 100% active electrically. Group IIIB elements, indium in particular, are easily incorporated from both solutions. Indium doping from tellurium-rich melts, however, has one advantage in that the segregation coefficient is near unity.

Astles [14.22] has reviewed the experimental data of Te-rich LPE growth at 460 to 550 °C. As an exam-

ple, to compare growth parameters for Te solutions with those for Hg solutions, consider the growth of LWIR MCT ($x = 0.2$) at 500 °C from both Te and Hg solutions. The x_{Cd} for Te-rich solutions is 8.3×10^{-3} , while x_{Cd} for Hg-rich solutions is 2.6×10^{-4} . This is one of the difficulties encountered in LPE growth from Hg-rich solutions. Use of large melts, however, overcomes the Cd depletion problem. MCT epitaxial layers of the desired thickness ($> 10 \mu\text{m}$) and of uniform composition through the thickness can be grown.

A typical sliding-boat arrangement has been described by Capper et al. [14.29]. The LPE boat is made from purified, high-density, small-grain, electronic-grade graphite. The precompounded growth solution is placed in a growth well, and crushed HgTe is placed in a blind well. The HgTe acts as a buffering source for the volatile elements to help stabilize the growth solution composition and also to deliver an overpressure to the annealing well to control the metal vacancy level during annealing. These wells are connected to the annealing well with a gas channel plate that controls the movement of the volatile elements within the boat. The growth solution and HgTe overpressure source are made from high-purity elements. The control over the impurity levels in the major constituent elements is a crucial part of the control of the overall process.

At the start of the growth cycle the slider is positioned so that the substrate is under the annealing well. The loaded boat is placed in the reactor tube and the furnace is pre-heated to 520 °C and then moved over the boat. The boat heats rapidly, and after a solution melting and equilibration period, the furnace is cooled rapidly by $\approx 20^\circ\text{C}$, and then a slow cooling ramp (2 or 3 °C/h) is initiated. When the boat reaches the required growth start temperature, the slider is moved so that the substrate is positioned under the molten solution. The ramp continues until the required film thickness has been grown, after which the slider is returned to the starting position and the furnace temperature reduced rapidly to an annealing temperature. Following the anneal, the furnace is moved back to its starting position and the system is allowed to cool.

Surface morphology is controlled at two levels: microtexture and long-range variation. The microtexture is a result of misalignment of the substrate crystal plane with the growing surface. Deviations $> 0.1^\circ$ from the $\langle 111 \rangle_B$ plane lead to significant surface texture. Growth on accurately orientated substrates gives a specular surface on which atomic-scale growth features can be seen using atomic force microscopy (AFM). Figure 14.8 shows a clas-

Fig. 14.8 AFM image of a Frank-Read growth spiral. (After [14.26])

sical Frank–Read site on an as-grown LPE layer surface.

The approach to forming p-on-n DLHJ structures by LPE is virtually universal. LPE from Hg-rich solution is used to grow the As- or Sb-doped p-type cap layers. The In-doped n-type base layers are grown by various Te-melt LPE techniques including tipping, sliding, and dipping. The trend appears to be in favor of the p-on-n DLHJ structures, as passivation is more controllable than that of the n-on-p structures [14.30]. A bias-selectable two-color (LWIR/MWIR) detector structure was first fabricated by growing three LPE layers from Hg-rich melts in sequence on a bulk CdZnTe substrate, Casselman et al. [14.31].

Other Narrowgap II–IV Compounds

HgZnTe was first proposed as an alternative detector material to MCT due to its superior hardness and its high energies for Hg vacancy formation and dislocation formation [14.32]. Rogalski [14.33] reviewed the LPE growth of HgZnTe and noted that Te-rich growth is favored due to the low solubility of Zn in Hg and the high Hg partial pressure. He also commented that the same factors apply to the growth of HgMnTe. Bella et al. [14.24] grew HgMnTe in a two-temperature, closed-tube tipping arrangement at 550–670 °C onto CdMnTe bulk substrates and CdMnTe LPE layers previously grown on CdTe substrates. Phase diagram data were also presented and the value of k_{Mn} was quoted as 2.5–3. Rogalski [14.33] also reviewed the status of PC and PV detectors in both HgZnTe and HgMnTe.

14.1.8 Atomically Flat Surfaces

Chernov and Scheel [14.34] have argued that far from the perceived drawback of LPE of producing rough surfaces, it may be uniquely suited to providing atomically flat, singular surfaces over distances of several micrometers. These surfaces would have applications in surface physics, catalysis and improved homogeneity of layers and superlattices of semiconductors and superconductors.

In support of this view, Fig. 14.8 shows an AFM image of a Frank–Read growth spiral on the surface of an MCT layer grown by LPE in this author's laboratory [14.26].

14.1.9 Conclusions

LPE was generally the first epitaxial technique applied to most systems of interest in micro- and optoelectronics. It is now generally a mature technology, with large fractions of several optoelectronic, IR detectors and other device types being made in LPE material, although some developments are still taking place. LPE has several advantages over the various vapor-phase epitaxial techniques, such as high growth rates, favorable impurity segregation, ability to produce flat faces, suppression of certain defects, absence of toxic materials, and low cost. There is much less emphasis on LPE in the current literature than on the vapor-phase methods, but LPE continues to seek out and develop in several niche markets where vapor-phase techniques are not suitable.

14.2 Metalorganic Chemical Vapor Deposition (MOCVD)

14.2.1 Introduction and Background

The technique of MOCVD was first introduced in the late 1960s for the deposition of compound semiconductors from the vapor phase. The pioneers of the technique, Manasevit and Simpson [14.35] were interested in a method for depositing optoelectronic semiconductors such as GaAs onto different substrates such as spinel and sapphire. The near-equilibrium techniques such as LPE and chloride VPE were not suitable for nucleation onto a surface chemically very different to the compound being deposited. These pioneers found that if they used combinations of an alkyl organometallic for the Group III element and a hydride for the Group V element, then films of GaAs could be deposited onto a variety of different surfaces. Thus, the technique of

MOCVD was born, but it wasn't until the late 1980s that MOCVD became a production technique of any significance. This success depended on painstaking work improving the impurity of the organometallic precursors and hydrides. By this time the effort was on high-quality epitaxial layers on lattice-matched substrates, in contrast with the early work. The high-quality epitaxial nature of the films was emphasized by changing the name of the growth method to metalorganic vapor phase epitaxy (MOVPE) or organometallic VPE (OMVPE). All of these variants of the name can be found in the literature and in most cases they can be used interchangeably. However, MOCVD can also include polycrystalline growth that cannot be described as epitaxy. The early niche applications of MOVPE were with GaAs photocathodes, GaAs HBT lasers and

GaInAsP lasers and detectors for 1.3 μm optical fiber communications.

The characteristics of MOCVD that have taken it from a research curiosity to production have been in the simplicity of delivery of the reactive vapors and the versatility of compositions, dopants and layer thicknesses. These basic attributes have enabled the same basic technique to be used for narrow bandgap semiconductors such as the infrared detector materials $\text{Cd}_x\text{Hg}_{1-x}\text{Te}$ and GaInSb and now for wide bandgap semiconductors such as GaN and ZnO. Indeed, the success of GaInN in the 1990s for high-brightness blue LEDs has now led to this being the most popular material produced by MOCVD. The early strength of MOCVD was its ability to grow onto different substrates but this was later abandoned in favor of the more conventional heteroepitaxy; however, the nitrides rely on heteroepitaxy onto sapphire and SiC substrates, bringing MOCVD back to its roots with the early work of Manasevit. This versatility with substrate materials presents MOCVD with the ultimate challenge of mating high-performance optoelectronic materials with silicon substrates in order to combine the best of optoelectronic and electronic performance.

This section of the chapter will cover the key elements of the MOCVD process from the physical characteristics of the precursors through reactor design to getting the right materials properties for high-performance devices.

14.2.2 Basic Reaction Kinetics

The precursors for III–V MOCVD are generally a simply alkyl for the Group III source and a hydride for the Group V source. Both have the essential properties of being volatile in a suitable carrier gas stream (usually hydrogen) and being chemically stable at ambient temperature. These precursors are normally mixed outside the reaction chamber, introduced into the reaction chamber through a suitable injector arrangement and directed onto a hot substrate. This is shown schematically in Fig. 14.9. The details of reactor design will be discussed later in this chapter. The reaction of the precursors to yield the III–V compound on the substrate can occur either in the hot vapor above the surface or on the hot surface. The stoichiometric reaction for GaAs growth is given as

This reaction has been the most widely studied of all the MOCVD reactions and was one of the original processes reported by Manasevit and Simpson [14.35]. One

Fig. 14.9 Schematic of MOCVD process from mixing of gas streams to reaction on the substrate surface

Fig. 14.10 Reaction scheme for epitaxial deposition of GaAs showing the most important vapor phase and surface reaction steps

reason that it works so well is that the hydrogen required to satisfy the $\cdot\text{CH}_3$ radical bond is supplied from the arsine hydride, and at normal growth temperatures (around 700 $^\circ\text{C}$) avoids unsatisfied carbon bonds that could lead to carbon incorporation. In reality this very simple picture covers a complexity of reaction steps that have to take place, that have been discussed in great detail by Chernov [14.36]. However, some of the important reaction steps will be described here as an introduction to the kinetics of GaAs MOCVD.

The schematic shown in Fig. 14.10 gives some of the important reaction steps that have been identified for the reaction of GaAs. This gives some insight into the complexity of the reaction kinetics and it is worth remembering that this is a relatively straightforward reaction for MOCVD. Fortunately, one does not have to

understand every step in the process before attempting to grow a layer, and this goes some way to explaining why MOCVD has developed along very empirical lines. An understanding of the reaction kinetics does, however, enable some of the problems that are associated with MOCVD to be understood, particularly when these relatively simple precursors are replaced by more complex precursors.

It can be seen from Fig. 14.10 that the reaction process is started by gas-phase homolysis of TMGa $[(\text{CH}_3)_3\text{Ga}]$ to yield dimethylgallium and methyl radicals $(\cdot\text{CH}_3)$. There are two important roles that the methyl radicals can take and this is generally important in all MOCVD processes for deposition of III–V semiconductors:

1. Methyl radicals can react with the ambient hydrogen carrier gas to yield stable methane and hydrogen radicals.
2. Methyl radicals can react with the arsine (AsH_3) to yield stable methane and AsH_2 .

Both of these steps can initiate the decomposition of arsine either through either a methyl radical or a hydrogen radical removing a hydrogen atom from the arsine; these reaction steps can be seen in Fig. 14.10. There are some important consequences of these initial reaction steps, and one you may have already spotted is that the hydrogen carrier gas is not included in the stoichiometric reaction (14.1) but can play a part in the reaction process. Another consequence is that although it is highly unlikely that the two (or more) precursors have the same

thermal decomposition characteristics, they can be used together to react at the same temperature through radical reaction mechanisms. The latter has been illustrated in many studies of different systems using ersatz reaction tube experiments, and further information on these can be found in *Stringfellow* [14.37]. For example, in the case of GaAs, the pyrolysis of TMGa will occur at 500°C , but for arsine decomposition, a temperature of around 700°C is required.

The stepwise removal of ligands from TMGa and arsine can occur in the vapor or on the surface. Figure 14.10 shows both alternatives and the dominant path will depend on both the surface temperature and vapor temperature above the substrate. A general rule is that more of the reaction process will occur on the surface at lower temperatures when the vapor reaction rate will be slower and the surface adsorption will be more efficient. It is also important to note that there are two different adsorption sites on the surface: the Ga sites that will take the anion species and the As sites that will take the cation species.

Part of the early success of GaAs and the alloy GaAlAs was due to the absence of unwanted vapor-phase reactions that could lead to the formation of polymer chains that would contaminate the layer. This was not the case with InP where the liquid alkyl source TEIn was used instead of the solid TMIn. This led to a mist in the reactor resulting from the formation of an adduct between the precursors that subsequently polymerized. This was overcome through the use of low-pressure reactors, and this has remained a feature of most production reactors today. However, the preferred precursor is TMIn and the problems of uncertain supply from a solid source has been overcome by a variety of different innovative methods. One example is to form a liquid with a stable amine, and the source then will behave in the same way as any other liquid precursor (*Frigo et al.* [14.38]).

The details of the reaction kinetics will change with substrate temperature, but as the temperature is increased a point will be reached where the rate of epitaxial growth will no longer be determined by the overall reaction rate but will be determined by the supply of precursors to the substrate. This will be reflected by a depletion of the precursor concentration immediately above the surface and a gradient in precursor concentration towards the undepleted free stream. The limitation on the rate of epitaxial growth then becomes the rate of diffusion through the depleted boundary layer to the substrate. This is called transport-limited growth and is characterized by high growth rates and only a weak dependence of growth

Fig. 14.11 Schematic of the three different temperature regimes for growth of a compound semiconductor by MOCVD

rate on substrate temperature. This is shown schematically in Fig. 14.11. The plot is of $\ln(\text{growth rate})$ versus $1/T$ because of the expected Arrhenius relationship in the rate constants. This really only applies to the low-temperature (kinetic) regime. Here the growth rate can be expressed as

$$\text{Rate} = A \exp(-E_a/RT), \quad (14.2)$$

where A is a constant and E_a is the activation energy. It is unlikely that E_a can be attributed to the activation energy for a single reaction step, but it is still useful for characterizing the kinetics when different precursors are being tested.

In the transport-limited regime there will be a small dependence on temperature due to the increase in diffusion rate with temperature, and this is illustrated in Fig. 14.11. Most MOCVD growth processes will take place in the transport-limited regime where it is easier to control growth rate. However, there are a number of growth processes that will occur at lower temperatures in order to control the properties such as native defect concentrations of the epitaxial films. This is generally the case with II–VI semiconductors, but can also apply to the formation of thermodynamically unstable III–V alloys.

In the high-temperature regime, the growth rate decreases with temperature, as the equilibrium vapor pressure of the constituent elements in the film will increase and give desorption rates similar to the deposition rate, leading to significant loss of material through evaporation to the gas stream.

14.2.3 Precursors

The choice of precursors is not confined to simple alkyls and hydrides but can extend to almost any volatile organometallic as a carrier for the elemental components of a film. In the case of II–VI semiconductors it is usual to use an alkyl for both the Group II and the Group VI elements. Hydrides have been used as Se and S sources but prereaction makes it difficult to control the growth process and in particular can make it difficult to incorporate dopants. The use of combined precursor sources has been extensively researched but is not in common use for epitaxial device-quality material. One reason for this is the difficulty in controlling the precursor ratio that is needed to control the stoichiometry of the material.

The important properties of precursors, and their selection, can be generalized and provides a basis for optimizing the MOCVD process. These properties can be summarized as follows:

1. Saturated vapor pressure (SVP) should be in the range of 1–10 mbar in the temperature range 0–20 °C.
2. Stable for long periods at room temperature.
3. Will react efficiently at the desired growth temperature.
4. The reaction produces stable leaving groups.
5. Avoids unwanted side reactions such as polymerization.

According to the Clausius–Clapeyron equation, the SVP of a liquid is given by an exponential relationship:

$$\text{SVP} = \exp(-\Delta G/RT), \quad (14.3)$$

where ΔG is the change in Gibbs free energy on evaporation, R is the gas constant and T the temperature of the liquid in the bubbler. This can be expressed as the heat of evaporation ΔH and the entropy for evaporation ΔS , where $\Delta G = \Delta H - T\Delta S$; this gives the familiar form of the SVP equation:

$$\begin{aligned} \text{SVP} &= \exp(-\Delta H/RT) + \Delta S/R \\ &= \exp(\Delta S/R) \exp(-\Delta H/RT). \end{aligned} \quad (14.4)$$

This is of the form:

$$\log_e(\text{SVP}) = A - B/T, \quad (14.5)$$

where A and B are constants given by $A = \Delta S/R$ and $B = \Delta H/R$. Manufacturers of the precursors will generally give the SVP data in the form of the constants A

Table 14.1 List of precursors with vapor pressure constants derived according to (14.6)

Precursor	A	B	SVP at 20 °C (mm Hg)
TMGa	8.07	1703	182
TEGa	8.08	2162	5.0
TMAI	8.22	2134	8.7
TEAI	9.0	2361	0.02
TMIn	10.52	3014	1.7
TEIn	8.94	2815	1.2
Solution TMIn	10.52	2014	1.7
DMZn	7.80	1560	300
DEZn	8.28	2109	12
DMCd	7.76	1850	28.2
DES	8.184	1907	47
DMSe	9.872	2224	
DESe	8.20	2020	
DMTe	7.97	1865	40.6
DIPTe	8.29	2309	2.6

and B in (14.5). It can also be given in the form

$$\log_{10}(\text{SVP}) = A' + B'/T. \quad (14.6)$$

To convert the constants in (14.6) to (14.5), just multiply by $\ln 10$. Some examples of the SVP constants, along with the calculated SVP at 20 °C, for a number of typical precursors are shown in Table 14.1.

14.2.4 Reactor Cells

The design of reactor cells has formed a very important part of the development of MOVPE and has been crucial in scaling laboratory processes to large-scale production. The original research reactors fell into one of two groups, either the vertical reactor or horizontal reactor. These reactor designs are shown schematically in Fig. 14.12. The substrate is placed onto a graphite susceptor that is heated by either RF coupling via a coil surrounding the reactor, a resistance heater underneath the susceptor, or lamps placed underneath the susceptor. The reactor wall can be water-cooled or gas-cooled to minimize reaction and deposition onto these surfaces. Either of these reactor cells could be operated at at-

mospheric or reduced pressure. For reduced-pressure operation the reactor cell pressure would be typically a tenth of an atmosphere but a wide range of different pressures have been successfully used. Reduced pressure will increase the gas velocity and help to overcome the effects of free convection from a hot substrate. The forced convection parameter that is often quoted is the Reynolds number and is proportional to gas velocity. A high Reynolds number will ensure streamline flow, while at low Reynolds number the buoyancy effects of the hot substrate will take over and the gas flow will be dominated by free convection (characterized by the Grashof number) and become disorganized with recirculation cells. In transport-limited growth the exact nature of the gas flow will determine the uniformity of deposition and can also affect the defect concentration in the films due to particulates and reaction products being swept back across the growing surface. It is not normal to achieve the very high flow velocities and Reynolds numbers associated with turbulent flow in an MOVPE chamber, but the disorganized flow due to free convection is often (wrongly) referred to as 'turbulent flow'.

Another reason for using high flow velocities is to overcome the effects of depletion of the precursor concentration at the downstream end of the deposition region. For transport-limited growth the growth rate is limited by the rate of diffusion from the free stream to the substrate. This region is called the boundary layer and increases in thickness going downstream from the leading edge of the susceptor, as shown in Fig. 14.13. Some horizontal reactors are designed with a tilt in the susceptor so that the free cross-sectional area decreases and hence the flow velocity increases going downstream. This helps to flatten the boundary layer and ensure better uniformity.

Maintaining a boundary layer has a cost: the high utilization of expensive precursors and gases, as the

Fig. 14.12a,b Schematic of (a) horizontal and (b) vertical reactor cells

Fig. 14.13 Schematic of a boundary layer in a horizontal reactor

Fig. 14.14a–d Schematic of four different production reactor designs: (a) the Emcore (Veeco) Turbo-disc, (b) the Thomas Swan showerhead, (c) the Aixtron planetary, and (d) the EMF Vector flow reactor

flow throughput is typically very high and the proportion of precursors reacted in the region of the substrates is very low. This became a more serious problem when reactors were scaled to hold multiple wafers for production. These problems have been resolved with different solutions in the vertical and horizontal reactor configurations with the Emcore (now Veeco) turbo-disc reactor, the Thomas Swan showerhead reactor and the Aixtron planetary reactor. A fourth production-scale reactor de-

sign has recently been introduced by EMF, called the Titan, and works on the principle of atomic layer deposition (ALD), where the Group II and Group V gases are fed over the substrate surface separately. A common feature to all of these production reactor designs is that the substrates are rotated so that the concentrations of precursors and reactants arriving at the substrate do not have to be uniform across the surface, as a portion of the substrate will alternately experience high and low concentrations that will average out. Each of these reactor designs is shown schematically in Fig. 14.14.

The turbo-disc reactor, shown schematically in Fig. 14.14a, is a vertical reactor configuration but the boundary layer is kept to a narrow region above the susceptor by high-speed rotation that pumps the gas radially outwards due to viscous drag. The rotation speeds are up to 2000 rpm in order to create this lateral flow of the constituents above the substrate. This is continuously replenished from the slower downward gas stream, resulting in excellent uniformity of deposition across the wafers and a high utilization of the reactant gases (Tompa et al. [14.39]). The reactor pressure is typically around 100 mbar.

The showerhead reactor is another vertical reactor arrangement but it takes a different approach to overcoming free-convection currents and poor uniformity [14.40]. The precursors are introduced through a water-cooled showerhead placed just above the susceptor. The susceptor is rotated but typically at much lower speeds than for the turbo-disc reactor. The precursor distribution can be balanced across the width of the reactor to give a uniform supply of precursors.

The planetary reactor is a horizontal flow arrangement where the reactants enter at the center of rotation of the susceptor and flow outwards. This is an example of a fully developed flow where depletion of the reactants is occurring as the gases move away from the center and this will be accentuated by a decrease in the mean flow velocity as the gases move outwards [14.41]. This would normally give very poor uniformity but the planetary rotation mechanism will rotate each wafer on the platen so it will sample alternately high and low concentrations, giving uniform deposition. This approach has the advantage of high utilization of the precursors and the ability to extend the design to very large reaction chambers for multiple wafers, with the Aixtron 3000 reactor holding 95 2 inch-diameter wafers.

The fourth approach to multiple wafer deposition is the EMF Ltd vector flow epitaxy (VFE), which introduces the Group II and Group V precursors separately over a rotating susceptor platen, as shown in Fig. 14.14d.

The rotation of the platen will direct the gases across the wafers and out through separate exhausts, thus keeping the gases separate in the reactor chamber. This has the advantage of alternately dosing the surface with Group III and Group V precursors to grow the film from atomic layers, which in turn prevents prereaction between the precursors and maintains excellent film uniformity over the growth surface. This could be particularly important for compounds of nitrides and oxides where reduced pressure is normally required to avoid significant prereaction. The advantage of the **ALD** approach is that the reaction chamber can be operated at atmospheric pressure, which simplifies the operation of the system.

14.2.5 III–V MOCVD

This section will consider the range of III–V materials grown by **MOCVD** and the precursors used. Most of the III–V semiconductors can be grown from organometallics of the Group III element and hydrides of the Group V element. Exceptions to this will be noted where appropriate.

Arsenides and Phosphides

The most commonly studied alloy system is $\text{Al}_{1-x}\text{Ga}_x\text{As}$, which is used for **LEDs** and laser diodes from the near-infrared to the red part of the visible spectrum. This is a well-behaved alloy system with only a small change in lattice parameter over the entire composition range and it covers a range of bandgaps from 1.435 eV for GaAs to 2.16 eV for AlAs. One problem with this alloy is the sensitivity of aluminium to oxygen, which makes it extremely difficult to grow high-quality AlAs. Just 1 ppm of oxygen contamination will result in 10^{20} cm^{-3} incorporation of oxygen into $\text{Al}_{0.30}\text{Ga}_{0.7}\text{As}$ [14.42]. In addition to the normal **MOCVD** precautions of using ultrahigh-purity hydrogen carrier gas and ensuring that the moisture in the system is removed, the hydrides and organometallics also need to have extremely low oxygen contents. Precursor manufacturers have tended to keep to the simple alkyl precursors but to find innovative ways of reducing the alkoxide concentrations.

Alternative Group V precursors have been sought due to the high toxicity of arsine and phosphine. These hydride sources also suffer from the fact that they are stored in high-pressure cylinders and any leakage could result in the escape of large quantities of toxic gas. Alternative alkyl Group V sources have been extensively researched but only two precursors have proved to be suitable for high-quality epitaxial growth, tertiarybutyl-

arsine (**TBA**s) and tertiarybutylphosphine (**TBP**). These precursors only have one of the hydrogen ligands replaced with an alkyl substituent but they are liquid at room temperature rather than high-pressure gases. In the reactor chamber the likely reaction path is to form the hydride by a process called beta-hydrogen elimination. This entails one of the hydrogen atoms from the methyl groups satisfying the bond to As (or P) with a butene leaving group as shown below [14.43]:

This process is more likely to dominate at the normal growth temperature for transport-limited growth and it effectively yields the arsine precursor that can then react in the normal way. In the search for alternative alkyl precursors this proved to be an important factor, as the fully substituted alkyl arsenic sources tended to incorporate large concentrations of carbon, degrading the electrical properties of the film. The importance of the Group V hydride was discussed in Sect. 14.2.2 and it can be understood why **TBA** and **TBP** (for the phosphorus alloys) have proved to be good alternatives to the hydrides. However, it is fair to say that these have never been widely utilized due to much higher cost than the hydrides and poor availability.

An alternative for improved safety has been investigated more recently and relies on the same principle of reducing the toxic gas pressure in the event of a system leak. This alternative stores the hydride in a reversible adsorption system [14.44]. The adsorption system keeps the hydride at sub-atmospheric pressure and requires pumping to draw off the hydride when needed, making it inherently safer. One major advantage to this system, in addition to the inherent improvement in safety, is that the precursors and hence the precursor chemistry are unchanged in the reactor cell.

Other alloys commonly grown using **MOCVD** include $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$, which has a band gap of approximately 2 eV and is lattice-matched to GaAs. The quaternary alloy GaInAsP enables lattice-matching to InP substrates while controlling the bandgap in the 1.3 μm and 1.55 μm bands used for long-range fiber-optic telecommunications.

Antimonides

The antimonides cover an important range of bandgaps from the near-infrared to the mid-infrared bands, up to 5 or 6 μm . These compounds and alloys can be used in infrared detectors, thermophotovoltaic (**TPV**) devices and high-speed transistors. The growth of the antimonides is more complex than for the arsenides and phosphides be-

cause the hydride, stibine, is not very stable at room temperature so the use of alkyl precursors has been a more natural choice. Another factor that has influenced the growth of the antimonides is the lower thermodynamic stability and decomposition of substrates such as InSb above about 400 °C. It is also desirable to grow the films at a much lower temperature than for the arsenides and phosphides in order to keep the native defect concentration low for controlled n-type and p-type doping. However, the antimonides have an advantage in that they do not incorporate carbon as readily as in the arsenides and phosphides and there is greater flexibility over the choice of antimony precursors [14.45]. The easiest choice is to use trimethylantimony (TMSb) or to use larger alkyl groups such as triethyl and triisopropyl to reduce the reaction temperature as required. It is also possible to reduce the reaction temperature by replacing TMGa with triethylgallium (TEGa) [14.46]. This approach has been particularly advantageous when growing aluminium-containing alloys where carbon incorporation can be a problem, but is reduced using TEGa. This serves to illustrate the flexibility of MOCVD and has given more scope for the design of precursors, not envisaged in the early days of MOCVD.

Nitrides

The nitrides, mainly GaN and the alloy GaInN have brought MOCVD into prominence as a manufacturing technology with the success of high-brightness blue LEDs making large-screen full-color LED displays a reality. The precursors used for the nitrides are standard with the methyl alkyls (TMGa and TMIIn) for the Group III elements and ammonia for the nitrogen. The key technological barriers to obtaining device-quality GaN were to overcome the problems associated with heteroepitaxy onto a non-lattice-matched substrate, sapphire or SiC and to control p-type doping [14.47]. Some research has been carried out with homoepitaxy onto GaN substrates, but the very high pressures needed for bulk crystal growth of GaN will restrict the sizes of substrates available.

The heteroepitaxial problems have been overcome with a two-stage growth. High-quality GaN requires growth temperatures in excess of 1000 °C, much higher than is needed for the arsenides and phosphides. At these temperatures, nucleation onto sapphire is poor and large faceted islands grow before complete coalescence of the film occurs. This not only leads to very poor surface morphology but a high dislocation density where the islands coalesce. Two-stage growth overcomes this by growing a uniform nucleation (or buffer) layer onto the

sapphire at 600 °C. This is then heated to normal growth temperature, where a thicker GaN film is then grown. The whole nucleation process can be monitored in situ using laser reflectometry and an example is shown in Fig. 14.15 [14.48]. It can be seen that approximately 50 to 100 nm of GaN is grown as a smooth layer but during heating this changes to a rough layer. A remarkable part of the process is that during the high-temperature growth, shown in Fig. 14.15 by interference oscillations, there is a recovery in the surface morphology, resulting in smooth, device-quality layers. In some cases the GaN buffer layer is substituted with an AlN layer, but in all cases a two-stage growth process is required. The growth of device layers is achieved by controlling the band gap through growth of the alloys GaInN or GaAlN. The band gap of GaN is 3.4 eV, which is in the UV, so the color of the LED is determined by the alloy composition where increasing the In content will reduce the band gap and push the emission wavelength from blue to green. However, this is not an easy alloy to form due to the different stabilities of the GaN and InN bonds [14.49]. In fact, it cannot be grown to any useful In content at temperatures above 1000 °C, so the temperature must be reduced to around 800 °C. Even with this compromise, the different lattice parameters of GaN and InN result in poor solubility and In contents of more than 40% are not practical. In principle it is possible to prepare LEDs of any color by just changing the In content in the alloy, but in practice the high-brightness diodes can only be prepared from nitrides covering the blue to green portion of the spectrum. The growth of Al-containing alloys is

Fig. 14.15 Laser reflectometry of GaN nucleation and growth

desirable in order to achieve wider band gaps for applications such as **UV LEDs** and solar-blind detectors. The problems are similar to those of the In and Ga alloys, but in the case of Al and Ga the stability of AlN is much greater than that of GaN, which will tend to form AlN clusters. The growth of different alloy compositions, particularly the growth of higher In content GaInN, has stimulated some research on alternative precursors for nitrogen, as ammonia pyrolysis is not very efficient at temperatures below 800 °C. One of the favorite candidates is dimethylhydrazine, which will react readily with TMGa at temperatures down to 400 °C.

The reaction of the ammonia with the Group III alkyls to form adducts that can then polymerize is a problem associated with the high growth temperature. This requires special care over the introduction of the precursors, the control of gas flows and wall temperatures. A failure to adequately control these parasitic reactions will lead to poor growth efficiency, higher defect concentration in the GaN layer and poor dopant control. The dopants used for n-type and p-type GaN are Si from silane and Mg from dicyclopentadienylmagnesium. The n-type doping has proved to be fairly straightforward, but Mg doping results in the formation of Mg–H bonds that passivate the acceptor state. This problem was solved by annealing the epitaxial films after growth to remove the hydrogen. This is possible due to the thermal stability of GaN and the high mobility of hydrogen in the lattice. A further problem with p-type doping is that the Mg acceptor has an ionization energy of between 160 and 250 meV and only about 10% of the chemically introduced Mg is ionized at room temperature.

Despite the materials challenges of GaN and its alloys, **MOCVD** has enabled the production of a wide range of devices based on these alloys over the past decade, from high-power transistors to laser diodes. Both of these examples have required improvements in material quality and a reduction in the relatively high dislocation densities. In fact, the potential for nitrides is enormous as the quaternary GaInNAs can be tuned to around 1 eV with just 4% nitrogen and is a challenge to the use of InP-based materials for 1.3 μm telecommunications lasers.

14.2.6 II–VI MOCVD

The **MOCVD** of II–VI semiconductors is carried out at much lower temperatures than for their III–V counterparts and this has stimulated a wide range of research on alternative precursors, growth kinetics and energy-assisted growth techniques such as pho-

toassisted growth. The basic principles are the same as for III–V **MOCVD** and, in general, the same reaction chambers can be used but the lower growth temperatures have led to the development of new precursors, particularly for the Group VI elements. Hydrides are, in general, not used now but early work on ZnSe and ZnS used hydrogen selenide and hydrogen sulfide [14.50]. A strong prereaction occurred between the hydrides and dimethylzinc that could result in deposition at room temperature, but as with III–V **MOCVD**, prereactions can make it difficult to control the defect chemistry and the doping. These II–VI compounds and their alloys have been investigated as blue emitter materials with similar bandgaps to GaInN. Alternatively, ZnTe is a potential green emitter and the narrower bandgap tellurides are used for infrared detectors. In fact, the only commercial application of II–VI **MOCVD** has been for the fabrication of HgCdTe alloys for infrared detectors. However, the processes used are quite different to standard **MOCVD** and require different designs of reactor cells, as will be shown in the next section.

MOCVD of HgCdTe

HgCdTe is one of the few direct bandgap semiconductors suitable for infrared detection in the important 10 μm band. The alloy has only a 0.3% mismatch over the entire composition range and will cover the entire infrared spectrum from the near-infrared with CdTe to the far-infrared (HgTe is a semimetal so there is no lower limit to the band gap). The main difficulty with growing HgCdTe by **MOCVD** has been the very high equilibrium vapor pressure of Hg over the alloy even at relatively low temperatures. For example, **MBE** has to be carried out at temperatures below 200 °C. A further difficulty created by the instability of HgTe is that the tellurium-rich phase boundary, which represents the minimum Hg pressure required to achieve growth, has a high concentration of doubly ionized metal vacancies that make the material p-type. At typical **MOCVD** growth temperatures for HgCdTe, 350 to 400 °C, the equilibrium vapor pressure for Hg would have to be close to the saturated vapor pressure for liquid Hg in order to keep the metal vacancy concentration below the impurity background. This is clearly not realistic in **MOCVD** as the walls of the reaction chamber would have to be heated to the same temperature as the substrate to avoid mercury condensation, and this, in turn, would cause pyrolysis of the precursors before they arrived at the substrate. Fortunately, it is possible to grow HgCdTe film on the tellurium-rich phase boundary where the Hg

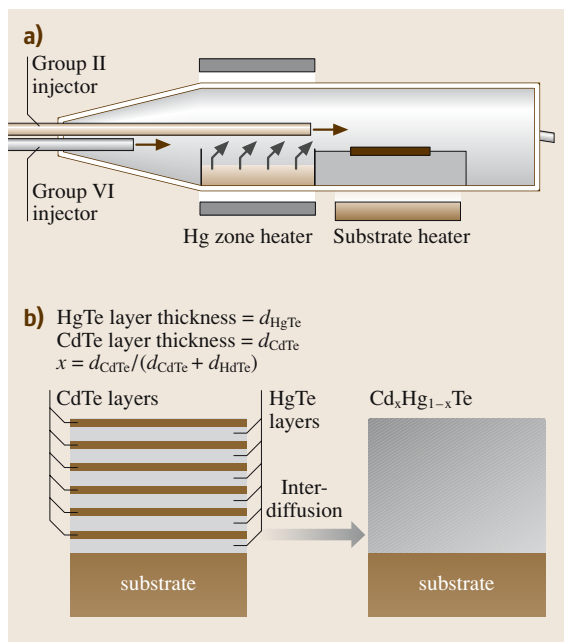

Fig. 14.16 (a) Schematic of MOCVD cell for HgCdTe growth, (b) schematic of IMP

source and reactor walls can be held at around 250 °C. At this temperature the pyrolysis of the Cd source, dimethylcadmium (DMCd), and the tellurium source, diisopropyltellurium (DIPTe), are sufficiently slow to minimize the premature reaction.

A schematic of an MOCVD reactor suitable for the growth of HgCdTe is shown in Fig. 14.16. The main features are the heating of the reactor wall and the internal source of liquid Hg. This is the only MOCVD process that uses an elemental source and is only possible because of the high vapor pressure of liquid Hg. In fact, a higher partial pressure can be achieved using the elemental source than an organometallic source, and this is the only metal where this is true. Another feature of this reactor cell is the injection of DMCd through the Hg source to avoid a radical exchange reaction between DMCd and Hg [14.51].

The alloy composition needs to be precisely controlled in order to control the detection wavelength of the infrared detector. For a 10 μm detector the proportion of Cd on the metal sub-lattice is 21% and it needs to be controlled to better than 0.5%. The reaction rates for CdTe and HgTe require different optimum flow rates, which makes simultaneous alloy control very difficult. This problem was overcome using the interdiffused multilayer process (IMP), where alternate layers

of HgTe and CdTe were grown and the flow rate optimized for each [14.52]. This process relied on very rapid Cd/Hg interdiffusion in the HgCdTe alloy, which enables complete homogenization of the alloy at the growth temperature. The composition is now simply controlled by the relative thicknesses of HgTe and CdTe, as shown schematically in Fig. 14.16b.

Sulfides and Selenides

Low-temperature growth of ZnSe (below 400 °C) has been achieved using ditertiarybutylselenide (DTBSe) with dimethylzinc (DMZn) or the adduct DMZn.TEN. The amine, triethylamine (TEN), was first introduced to suppress gas-phase reactions with the hydrides H₂Se and H₂S. However, this adduct has the additional advantage of reducing the saturated vapor pressure of DMZn and making it easier to manage. The significance of keeping the growth temperature low is to avoid deep-level native defects that act as trapping sites for donors and acceptors. The p-type doping of ZnSe with nitrogen was problematic due to hydrogen passivating the dopant. Incorporation of nitrogen from a variety of precursor sources such as amines and azides up to concentrations of 10¹⁸ cm⁻³ could be readily achieved but the active dopant concentration, in general, remained below 10¹⁵ cm⁻³. This was in contrast with the success of MBE growth of ZnSe that was doped from a nitrogen-plasma source. Fujita and Fujita [14.53] overcame this problem by ex situ annealing in a similar manner to GaN but the weaker lattice gives less scope for this treatment compared with GaN.

An alternative approach for low-temperature growth of ZnSe was to use short-wavelength light and UV wavelengths to illuminate the growing surface and promote surface photocatalytic reactions [14.54]. It was shown by Irvine et al. [14.55] that the reaction kinetics did not depend on the Se precursor, giving similar growth rates for DMSe, DESe and DIPSe, but depended on a hydrogen radical reaction that was initiated by a surface decomposition of the Group II precursor. Although this was effective for growing epitaxial films of ZnSe at temperatures well below 400 °C, it was clear that hydrogen incorporation was a natural consequence of the reaction mechanism.

MOCVD of Group II Oxides

A recent resurgence of interest in ZnO and related materials such as ZnMgO and ZnCdO has arisen because of the success of GaInN as a blue emitter and the potential for further developments with UV laser diodes and a solid state replacement for domestic lighting. GaInN white

light LEDs already exist but the efficiency of the phosphors would improve if they were excited with UV rather than blue photons. A further potential advantage of ZnO is that large ZnO single-crystal substrates can be grown by the hydrothermal method and would eventually avoid the defect problems associated with heteroepitaxy that have slowed progress with GaN.

All the early work on ZnO MOCVD used oxygen or water vapor as the oxygen source. These react strongly at room temperature with DMZn and DEZn. Although reasonably good quality ZnO films have been deposited with this approach, it is unlikely that it will lead to high-quality epitaxial growth or good doping control. Essentially, prereaction in all of the III–V and II–VI semiconductors has been a barrier to obtaining device-quality material. The favored alternative oxygen precursors are the alcohols: isopropanol and tertiarybutanol. For higher temperatures, N₂O is a suitable precursor. In general, for epitaxial growth on sapphire or ZnO substrates it is necessary to grow at temperatures above 600 °C, but for polycrystalline transparent conducting oxides (TCOs) these precursors can react at temperatures as low as 300 °C. It is possible to readily dope ZnO n-type using TMAI, but as with ZnSe it has been difficult to achieve p-type doping. Some encouraging results have been obtained using ammonia [14.56], but this work is still at an early stage of development and must be solved before electroluminescent devices can be made. This is proving

to be another class of materials where the versatility of MOCVD has a lot of potential for innovative solutions.

14.2.7 Conclusions

This section of the chapter has covered the basic principles of MOCVD and reviewed the range of III–V and II–VI semiconductors that can be grown in this way. This can be contrasted with LPE and MBE, where each method will have its own strengths and weaknesses for a particular material or application. The strength and the weakness of MOCVD is in its complexity. With the right precursors it is possible to deposit almost any inorganic material, but in many cases the reaction mechanisms are not well understood and the development is empirical, with the researcher spoiled by a very wide choice. This is not to deny the very considerable successes that have led to major industries in compound semiconductors that has been epitomized in the past 10 years by the production of GaN and the plethora of large LED displays that would not have been possible without MOCVD. Without the pioneering work of *Manasevit* and *Simpson*, who demonstrated the potential to grow so many of these materials in the early years, and the fortuitous ease with which GaAs/AlGaAs could be grown, we might not have tried so hard with the more difficult materials and hopefully we will see many more innovations in the future with MOCVD.

14.3 Molecular Beam Epitaxy (MBE)

14.3.1 Introduction and Background

MBE is conceptually a very simple route to epitaxial growth, in spite of the technology required, and it is this simplicity that makes MBE such a powerful technique. It can be thought of as a refined form of vacuum evaporation, in which neutral atomic and molecular beams from elemental effusion sources impinge with thermal velocities on a heated substrate under ultrahigh vacuum (UHV). Because there are no interactions within or between the beams, only the beam fluxes and the surface reactions influence growth, giving unparalleled control and reproducibility. Using MBE, complex structures can be grown atomic layer by atomic layer, with precise control over thickness, alloy composition and intentional impurity (doping) level. UHV confers two further advantages: cleanliness, because the partial pres-

sures of impurities are so low, and compatibility with in situ analytical techniques – essential to understanding the surface reaction kinetics. The basic elements of an MBE system are shown schematically in Fig. 14.17. A number of reviews [14.57–59] and books [14.60, 61] have discussed the physics, chemistry, technology and applications of MBE.

The technique that became known as MBE evolved from surface kinetic studies of the interaction of silane (SiH₄) beams with Si [14.62] and of Ga and As₂ beams with GaAs [14.63]. *Cho* and coworkers, who first used the term molecular beam epitaxy, demonstrated that MBE was a viable technique for the growth of III–V material for devices, leading the way for a worldwide expansion of effort.

Much early MBE equipment had a single vacuum chamber for loading, deposition and analysis, which

led to prolonged system pumpdown between growths. The technique required significant improvements in vacuum conditions before very high quality thin films were grown. *Cho* surrounded the effusion cells with a liquid nitrogen cryopanel to give thermal isolation and reported the MBE growth of thin films of n- and p-type GaAs for device purposes [14.64] and of GaAs/AlGaAs heterostructures [14.65]. The introduction of a substrate-exchange load lock [14.66] drastically reduced pumpdown times and reduced contamination of the deposition chamber. The installation of extensive internal liquid nitrogen-cooled cryopanel [14.67] substantially increased the pumping of oxygen containing species and permitted the growth of AlGaAs with superior quality. *Tsang* [14.68] demonstrated lasers with threshold current densities superior to those grown by LPE. Uniform growth over a 2"-diameter wafer was achieved by the introduction of a rotating substrate holder capable of 5 rpm [14.69]. Advanced forms of these features are now standard on commercial MBE systems, many of which feature a modular design. The technology of MBE is now mature, with increasing numbers of ever larger high-throughput, multiwafer production MBE machines in widespread use since the early 1990s.

MBE has been used to grow a wide range of materials, including semiconductors, superconductors, metals, oxides, nitrides and organic films. In almost all cases there is a drive to produce structures with ever smaller dimensions, whether for higher-performance devices, quantum confinement or, more recently, nanotechnology. This is longest established in III-V semiconductors, from the GaAs/AlGaAs superlattice [14.70] through quantum wells (QWs) and modulation doping to quantum wires and quantum dots [14.71]. Such low-dimensional structures form the basis of the QW lasers and p-HEMTs produced in huge volumes by MBE for optoelectronic and microwave applications. The combination of precise growth control and in situ analysis makes MBE the preeminent technology used to meet such demands.

14.3.2 Reaction Mechanisms

One of the first and most important of the in situ analytical techniques to be used in MBE is reflection high-energy electron diffraction (RHEED). From an early stage [14.72] it was used to determine the surface structure of the clean substrate and growing layer. This revealed that, in general, all surfaces are reconstructed (they have a lower symmetry than the bulk),

Fig. 14.17 Schematic diagram of an MBE growth chamber, showing the effusion cells and shutters, the substrate stage and the arrangement of the RHEED system

and *Cho* was the first to propose that the two-fold periodicity observed in the $[110]$ direction on the (001) surface was the result of dimerization of As atoms on the arsenic-terminated surface, which was confirmed many years later by scanning tunneling microscopy [14.73]. RHEED is a forward-scattering technique and therefore more compatible with the MBE arrangement of normally incident fluxes than the back-scattering geometry of LEED.

A further application of RHEED is the in situ measurement of growth rate. It was found [14.74,75] that the intensity of any diffraction feature oscillated with a period corresponding to the growth of a single monolayer (ML) – a layer of Ga + As – in the $[001]$ direction on a (001) substrate. These oscillations arise from surface morphological changes during two-dimensional (2-D) layer-by-layer growth, the Frank–van der Merwe mode, and a typical result for GaAs is shown in Fig. 14.18. The exact origin of the oscillations is still the subject of debate [14.59], but the technique was found to be applicable to many other material systems, including elemental semiconductors, metals, insulators, superconductors and even organic compounds.

Thus RHEED provided information on surface reconstruction and quantitative measurements of growth dynamics, which could be combined with those from other in situ techniques and related to theoretical treatments. In the early 1970s, the surface chemistry involved

Fig. 14.18 Diagram illustrating the development of RHEED intensity oscillations during 2-D layer-by-layer growth, together with an actual experimental plot (courtesy of B. A. Joyce)

in the MBE growth of III-V compounds was studied extensively using a combination of RHEED and modulated molecular beam mass spectrometry [14.76] or temperature-programmed desorption [14.77].

Detailed information was obtained on surface reactions involving gallium and arsenic. It was found that

the dissociation of GaAs results in the desorption of As_2 , and not of As or As_4 [14.78], and that a significant amount of desorption takes place at MBE growth temperatures. The sublimation of elemental arsenic, as from an effusion cell, results in the formation of As_4 alone. It was also shown that growth from $\text{Ga} + \text{As}_2$ is a first-order reaction (Fig. 14.19), whereas growth from $\text{Ga} + \text{As}_4$ is second-order [14.79, 80]. These results suggest that in MBE growth Ga sticks to available As sites and chemisorption of As_2 occurs on available Ga atoms. Chemisorption of As_4 occurs with two As_4 molecules interacting on adjacent Ga atoms. The sticking coefficient of As_4 is observed to be less than or equal to 0.5, whereas the sticking coefficient of As_2 can be equal to one, in agreement with this model. This implies that maximum coverage will be less than 100%, since single Ga sites cannot be occupied, and that As vacancies will be introduced into material grown using As_4 . This was thought to be responsible for the higher deep-level concentrations observed, which were found to be reduced when As_2 was used or at higher growth temperatures. It is now known that above 580°C As_4 dissociates to As_2 on the surface [14.81].

Detailed models were established for the growth of GaAs [14.79, 80] and AlAs [14.82]. With minor modifications these models are also valid for ternary alloys

Fig. 14.19 Surface chemistry of the growth of GaAs from As_2 and Ga (courtesy of B. A. Joyce)

such as AlGaAs [14.83]. It was established that growth rate depends solely on the net Group III flux (incident flux minus desorbing flux), and that ternary alloy composition can be controlled by adjusting the ratio of the Group III fluxes provided the thermal stabilities of both of the binary compounds that make up the alloy are considered. The Group V element need only be supplied in excess. The situation is more complicated for alloys containing both arsenic and phosphorus, since the presence of one Group V element influences the sticking coefficient of the other. *Foxon et al.* [14.84] found that phosphorus has a much lower incorporation probability than arsenic.

More recent studies have made use of in situ STM and more powerful theoretical treatments to consider nucleation and growth at the atomistic level, but the basic models are still sound.

14.3.3 MBE Growth Systems

The UHV system required for MBE is of conventional stainless steel construction, with an ultimate or background vacuum of less than 5×10^{-11} torr achievable with a clean system after baking, and with the liquid nitrogen cryopanels filled. At such a pressure the molecules have a typical mean free path of 10^6 m and so only suffer collisions with the internal surfaces of the system. It would take several hours to build up a monolayer of impurity on the wafer surface.

Oil-free pumping is used to eliminate the possibility of contamination by hydrocarbon backstreaming; typically rough pumping is with sorption pumps and UHV pumping is with ion pumps and titanium sublimation pumps. Diffusion pumps or turbomolecular pumps can be used, however, provided suitable cold traps are fitted, and such pumps are required for the higher gas loads involved in GSMBE and CBE. A two- or three-stage substrate entry load-lock and preparation chamber isolated by gate valves is used to minimize the exposure of the system to air. In modular systems, further deposition and analysis chambers may be added to the system and samples are transferred via the preparation chamber under UHV conditions.

The growth chamber substrate stage is surrounded by a large liquid nitrogen-cooled cryopanel, which has a high pumping speed for H_2O , CO , O_2 and other condensable species. This is arranged so that the heated (500 – 700°C) substrate is not directly exposed to thermal sources other than the molecular beams themselves, and impurities emanating from any other source can only reach the substrate after suffering at least one colli-

sion with, and probable adsorption by, a surface at liquid nitrogen temperatures. The cryopanel also reduces contamination arising from outgassing from the walls of the chamber that are exposed to radiation from the effusion cells.

Control over the composition and doping levels of the epitaxial layers is achieved by precise temperature control of the effusion cells and the use of fast-acting shutters in front of these cells. In most systems, the growth rate is about 1 monolayer per second, and the shutter operation time of 0.1 s thus corresponds to less than a monolayer of growth. A growth rate of one monolayer per second closely approximates one micrometer per hour for GaAs/AlGaAs.

Although often referred to as K-cells, the solid-source effusion cells used in MBE growth have a large orifice so as to obtain a high flux at reasonable temperatures. A true Knudsen cell has a very small outlet orifice compared to the evaporating surface, so that an equilibrium vapor pressure, typically 10^{-3} torr, is maintained within the cell. The diameter of this orifice is less than one tenth of the molecular mean free path, which is typically several centimeters. Under these conditions, a near approximation to ideal Knudsen effusion is obtained from the cell, giving molecular flow with an approximately cosine distribution. The flux from such a cell can be calculated quite accurately, but a high temperature is required to produce a reasonable growth rate; for example a gallium Knudsen cell would need to be at 1500°C to produce the same flux as an open-ended effusion cell at 1000°C . The lower operating temperature helps to reduce impurities in the flux and puts a lower thermal load on the system. The beam from an open-ended cell may not be calculable with any degree of accuracy but it is highly reproducible. Once calibrated via growth rate, normally by in situ measurement, the flux can be monitored using an ion gauge located on the substrate stage.

A number of effusion cells can be fitted to the growth chamber, generally in a ring facing towards the substrate with the axis of each cell at an angle of 20 – 25° to the substrate normal. Simple geometrical considerations therefore dictate the best possible uniformity that can be achieved with a stationary substrate [14.85]. Associated with each cell is a fast-action refractory metal shutter with either pneumatic or solenoid operation.

Uniformity of growth rate for a binary compound can be achieved by rotating the substrate at speeds as low as a few rpm, but compositional uniformity of ternary or quaternary alloys requires rotation of the substrate at speeds of up to 120 rpm (normally rotation is timed

so that one rotation corresponds to the growth of one monolayer). The mechanical requirements for a rotating substrate stage in a UHV system are quite demanding, as no conventional lubricants can be used on the bearings or feedthroughs and yet lifetime must exceed several million rotations. Magnetic rotary feedthroughs have largely replaced the earlier bellows type.

The need to rotate the substrate to give uniformity also leads to complications in substrate temperature measurement. The substrate is heated by radiation from a set of resistively heated tantalum foils behind the substrate holder, and both the heater and the thermocouple are stationary. Without direct contact between the thermocouple and the wafer the “indicated” thermocouple temperature will be very different from the “actual” substrate temperature. Some form of calibration can be obtained by using a pyrometer, although problems with window coating, emissivity changes and substrate transparency below the bandgap impose limits on the accuracy of such measurements. Alternatively, a number of “absolute” temperature measurements can be obtained by observing transitions in the **RHEED** pattern, which occur at reasonably fixed temperatures. However, such transitions occur in the lower temperature range and extrapolation to higher growth temperatures is not completely reliable. If the substrate is indium bonded to a molybdenum block (using the surface tension of the indium to hold the substrate), then inconsistencies in wetting can lead to variations in temperature across the substrate. Most modern systems and all production machines use “indium-free” mounting, which avoids these problems. However, the substrate is transparent to much of the **IR** radiation from the heater, putting a higher thermal load on the system.

The substrate preparation techniques used prior to **MBE** growth are very important, as impurities on the surface provide nucleation sites for defects. Historically, various chemical clean and etch processes were used, but wafers are now usually supplied “epi-ready”, with a volatile oxide film on the surface that protects the surface from contamination and can be thermally removed within the UHV chamber. **RHEED** is used to confirm the cleanliness of the surface prior to growth.

Historically, one of the major problems in **MBE** was the presence of macroscopic defects, with a typical density of 10^3 – 10^5 cm⁻², although densities below 300 cm⁻² were reported for ultraclean systems [14.86]. Defects are generally divided into two types; small hillocks or pits and oval defects. Such defects are a serious obstacle to the growth of material for integrated circuits, and considerable effort was devoted to the

problem. Oval defects are microtwin defects originating at a local imperfection, oriented in the (110) direction and typically 1 to 10 μm in length [14.87]. There are several possible sources of these defects, including foreign impurities on the substrate surface due to inadequate substrate preparation or to oxides from within the system, and possibly from the arsenic charge or the condensate on the cryopanel. The fact that oval defects were not seen when graphite crucibles were used but were common with PBN crucibles suggests that gallium oxide from the gallium melt is a major source of such defects since oxides would be reduced by the graphite. *Chai and Chow* [14.88] demonstrated a significant reduction in defects by careful charging of the gallium source and prolonged baking of the system. The irregular hillocks and pits seen in **MBE**-grown material were probably produced by microdroplets of gallium spitting from the effusion cells on to the substrate surface [14.89]. Gallium spitting can be caused by droplets of Ga that condense at the mouth of the effusion cell, fall back into the melt and explode, ejecting droplets of liquid Ga, or by turbulence in the Ga melt due to uneven heating that causes a sudden release of vapor and droplets.

Continuous developments in the design of Group III effusion cells for solid-source **MBE** have largely eliminated the problem of macroscopic defects. Large-area Ta foil K-cell heaters have reduced the uneven heating of the PBN crucible; the use of a “hot-lipped” or two-temperature Group III cell, designed with a high-temperature front end to eliminate the condensation of gallium metal at the mouth of the cell, significantly reduced the spitting of microdroplets. Combined with careful procedures and the use of an arsenic cracker cell, defect densities as low as 10 cm⁻² have been reported [14.90].

There have also been developments in the design of Group V cells. A conventional arsenic effusion cell produces a flux of As₄, but the use of a thermal cracker to produce an As₂ flux resulted in the growth of GaAs with better optical properties and lower deep-level concentrations [14.91]. In the case of phosphorus, growth from P₂ was strongly preferred to that from P₄ for several reasons [14.92], and this was one reason behind the development of **GSMBE** described below. However, the use of phosphine requires suitable pumping and safety systems. The Group V cracker cell has two distinct zones. The first comprises the As or P reservoir and produces a controlled flux of the tetramer; this passes through the second – high-temperature – zone, where dissociation to the dimer occurs. Commercial

high-capacity cracker cells, some including a valve between the two zones to allow fast switching of Group V flux, have been developed for arsenic and phosphorus.

Commercial MBE systems have increased throughput with multiwafer substrate holders, cassette loading and UHV storage and preparation chambers linked to the growth chamber with automated transfer, while increased capacity effusion cells have reduced the downtime required for charging. In some cases additional analytical and processing chambers have been added to permit all-UHV processing of the device structure.

14.3.4 Gas Sources in MBE

A number of MBE hybrids were developed that combined the advantages of UHV deposition and external gas or metalorganic sources to produce a versatile technique that has some advantages over MBE and MOVPE. These techniques utilize the growth chambers developed for MBE and pumping systems with a high continuous throughput, typically liquid nitrogen-trapped diffusion pumps or turbomolecular pumps. Layers are deposited from molecular beams of the precursor materials introduced via gas source cells that are essentially very fine leak controllers. As in MBE, there are no interactions within or between beams and the precise control of beams using fast-acting gas-line valves is therefore translated into precise control of the species arriving at the substrate. Shutters are not generally required; atomically sharp interfaces and monolayer structures can be defined as a consequence of submonolayer valve switching times.

Panish [14.93] investigated the use of cracked arsine and phosphine in the epitaxial growth of GaAs and InP, later extending this work to the growth of GaInAsP, and suggested the name gas source MBE (GSMBE). The major advantage of gaseous Group V sources was that the cracker cells produced controllable fluxes of the dimers As₂ and P₂, giving improved control of the As:P ratio. The MBE growth of high-quality GaAs from cracked arsine and elemental gallium was demonstrated at the same time by Calawa [14.94].

The extension to gaseous Group III sources was made by Veuhoff et al. [14.95], who investigated the MOCVD of GaAs in a simple MBE system using trimethylgallium (TMGa) and uncracked arsine. Further study showed that cracking of arsine at the substrate surface was negligible, leading to the conclusion that unintentional cracking of the arsine had taken place in the inlet system. The acronym metalorganic MBE (MOMBE) was used to describe GaAs growth from

TMGa and cracked arsine in a modified commercial MBE system [14.96].

The growth of device-quality GaAs, InGaAs and InP from alkyl sources of both Group III and Group V elements was demonstrated by Tsang [14.97], who used the alternative acronym chemical beam epitaxy (CBE). The use of Group V alkyls, which had much poorer purity than the hydrides, was undertaken for safety reasons [14.98]. Material quality was improved when cracked arsine and phosphine were used [14.99]. RHEED observations indicated that reconstructed semiconductor surfaces could be produced prior to growth, as for MBE [14.100], and GaAs/AlGaAs quantum well structures were demonstrated that were comparable with those grown by MBE or MOVPE [14.101].

Almost all of this work was with III–Vs, where MOMBE/CBE was seen to have several significant advantages over MBE while retaining many of its strengths, including in situ diagnostics. The use of vapor Group III sources would avoid the morphological defects associated with effusion cells, and higher growth rate and greater throughput could be achieved. Both Group III and Group V sources were external, allowing for easy replacement without the need to break vacuum. Flux control with mass flow controllers (MFCs) and valves would improve control over changes in composition or doping level, since flow could be changed faster than effusion cell temperature. Abrupt changes could thus be achieved that would require switching between two preset effusion cells in MBE (a problem when the number of cells was limited by geometry). It also offered improved long-term flux stability and greater precursor flexibility. As this was still a molecular beam technique, precise control over layer growth and abrupt interfaces would be retained, without any of the gas phase reactions, boundary layer problems or depletion of reagents associated with MOVPE. Other advantages included improved InP quality using a P₂ flux, lower growth temperatures and selective-area epitaxy.

There was, however, a price to pay in system complexity, with the need for gas handling and high-volume pumping arrangements added to the expensive UHV growth chamber. These would have been acceptable if CBE had demonstrated clear advantages, but there were a number of other issues. The standard Al and Ga precursors used in MOVPE (trimethylaluminum and trimethylgallium) produced strongly p-type material when used in CBE, due to the incorporation of C as an acceptor. Triethylgallium proved to be a viable Ga source, but alloy growth was more complicated; no universally acceptable Al source was found, while InGaAs

growth was found to be strongly temperature-dependent. The surface chemistry associated with metalorganic sources proved complex and the temperature dependence of surface reactions not only restricted growth conditions, but also had a serious impact on uniformity and reproducibility, particularly for quaternary alloys such as GaInAsP [14.102]. The lack of suitable gaseous dopant sources, particularly for Si, was a further handicap [14.103], but the deliberate use of C for p-type doping proved a success and this was transferred to MBE and MOVPE. Carbon diffuses significantly less than the 'standard' MBE and MOVPE dopants, Be and Zn, respectively [14.104], and proved an ideal dopant for thin highly doped layers such as the base region in heterojunction bipolar transistors (HBTs) and for p-type Bragg reflector stacks in vertical cavity surface-emitting laser structures (VCSELs).

GSMBE remains important, not in the III–V field where, with some exceptions [14.105], the development of high-capacity Group V cracker cells provided an easier route to an As₂ and P₂ flux, but in the III–nitride field. There are two major routes to nitride MBE: active nitrogen can be supplied by cracking N₂ in an RF or ECR plasma cell, or ammonia can be injected and allowed to dissociate on the substrate surface. In contrast, CBE has not demonstrated a sufficient advantage over its parent technologies to be commercially successful, particularly as both MOVPE and MBE have continued to develop as production techniques.

14.3.5 Growth of III–V Materials by MBE

Although they were amongst the earliest materials to be grown by MBE, GaAs-based alloys retain great importance, with MBE supplying materials for the mass production of optoelectronic and microwave devices and leading research into new structures and devices.

GaAs/AlGaAs

AlGaAs is an ideal material for heterostructures, since AlAs has a greater bandgap than GaAs and the two have negligible mismatch ($\approx 0.001\%$). The growth rate in MBE depends on the net Group III flux, with one micrometer per hour corresponding to a flux of 6.25×10^{14} Ga (or Al) atoms $\text{cm}^{-2}\text{s}^{-1}$. At low growth temperatures, all incident Group III atoms are incorporated into the growing film, together with sufficient arsenic atoms to maintain stoichiometry, and excess arsenic atoms are desorbed. However, III–V compounds are thermally unstable at high temperatures. Above ≈ 600 K [14.79] arsenic is preferentially desorbed, so an excess arsenic

flux is required to maintain stoichiometry. At higher temperatures, loss of the Group III element becomes significant, so that the growth rate is less than would be expected for the incident flux. This is particularly important for the growth of AlGaAs, where growth temperatures above 650°C are generally used to give the best optical properties. The Ga flux must be significantly increased above that used at lower temperatures in order to maintain the required composition of the alloy.

Typical growth temperatures for MBE of GaAs are in the range $580\text{--}650^\circ\text{C}$ and material with high purity and low deep-level concentrations has been obtained in this temperature range [14.106, 107]. The commonly used dopants, Be (p-type) and Si (n-type), show excellent incorporation behavior and electrical activity at these temperatures and at moderate doping levels. As was noted above, for highly doped layers Be has largely been replaced by C, which diffuses somewhat more slowly. At doping levels above $\approx 5 \times 10^{17}$, Si occupies both Ga (donor) and As (acceptor) sites, producing electrically compensated material with a consequent reduction in mobility. It is still predominantly a donor, however, and is the best available n-type dopant. The electrical properties of GaAs also depend on the As/Ga flux ratio, since this influences the site occupancy of dopants. The optimum As/Ga ratio is that which just maintains As-stabilized growth conditions, which can be determined using RHEED observations of surface reconstruction.

MBE-grown GaAs is normally p-type, the dominant impurity being carbon [14.108]. The carbon concentration was found to correlate with CO partial pressure during growth [14.109] – CO is a common background species in UHV, being synthesized at hot filaments. The lowest acceptor levels commonly achieved are of the order of $5 \times 10^{13} \text{ cm}^{-3}$, and such layers can be lightly doped to give n-type material with high mobilities. However, very high purity GaAs has been produced by adjusting the operating conditions for an arsenic cracker cell [14.110], which suggests that carbon contamination originates from hydrocarbons in the As charge. Unintentionally doped GaAs was n-type with a total impurity concentration of $< 5 \times 10^{13} \text{ cm}^{-3}$ and a peak mobility of $4 \times 10^5 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 40 K, the highest reported for n-type GaAs. The 77 K mobility of $> 200\,000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ is comparable with that for the highest purity GaAs grown by LPE [14.111].

MBE is capable of the growth of very high-quality material for structures whose physical dimensions are comparable to the wavelength of an electron (or hole) so that quantum size effects are important. Such structures have typical layer thicknesses from 100 \AA down to

2.8 Å, the thickness of a monolayer of GaAs, and have doping and composition profiles defined on an atomic scale. These low-dimensional structures have become very important in III–V device technology, one example being the modulation-doped heterojunction.

The precise control of growth that is possible is demonstrated by the very high mobilities obtained for modulation-doped structures grown by MBE. The modulation-doped GaAs/AlGaAs heterojunction has a band structure that causes carriers from the highly doped AlGaAs to be injected into a thin undoped region in the GaAs (Fig. 14.20a). Since the carriers are then separated from the donor atoms that normally scatter them, and confined in a quantum well as a two-dimensional electron gas (2DEG), very high mobilities can be achieved. Through suitable design of the structure and the use of lightly doped AlGaAs, a GaAs/AlGaAs 2DEG structure was produced with a peak mobility of $1.1 \times 10^7 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 1.3 K and a 4 K mobility of $4.5 \times 10^6 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and with a sheet carrier concentration of 10^{12} cm^{-2} [14.112]. GaAs layers grown in the same machine typically exhibited 77 K mobilities of the order of $100\,000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. Similar results can be obtained by delta doping the AlGaAs, that is by confining the Si donor atoms to a single monolayer in the AlGaAs separated by a few nm from the well, a technique with a wide range of applications [14.113].

The major application of this structure for device purposes is the high electron mobility transistor (HEMT), also known as the modulation-doped FET (MODFET), an FET in which the carriers are confined to the two-dimensional layer (Fig. 14.20b). The main advantage of the HEMT is not the increase in mobility, which is modest at room temperature for a practical device, but the very low noise when it is operated as a microwave amplifier, due to the reduction in impurity scattering. The HEMT is an essential component of many microwave systems, including mobile phones and satellite TV receivers.

MBE became used as a production technology for GaAs-based devices because of the excellent uniformity and reproducibility possible, and because the extensive UHV load-lock system of a production machine permits a large number of runs to be undertaken on a continuous basis. This was demonstrated as early as 1991 by a number of manufacturers producing both HEMTs and GaAs/AlGaAs lasers [14.114]. By 1994 some 5 million MQW lasers for compact disc applications were produced per month by MBE. Other devices included HEMTs and InAs Hall sensors. A comparison of production costs made at this time [14.115] showed that

Fig. 14.20a,b Schematic diagrams of the band structure (a) and physical arrangement (b) of the high electron mobility transistor (HEMT)/modulation-doped FET

capital costs for MBE were very similar to those for MOVPE, which required costly safety systems for the hydride gases, while MBE costs per wafer were somewhat less than for MOVPE. The growth in demand for HEMTs for mobile phones drove a further expansion in production MBE, although MOVPE remained dominant in InP-based optoelectronic devices.

InGaAs

InGaAs is generally grown at lower temperatures than GaAs/AlGaAs because of the higher rate of In desorption. Both InGaAs and the quaternary InGaAsP can be lattice-matched to InP substrates; heterostructures in these materials form the basis of the 1.3 μm and 1.55 μm optoelectronic devices used in telecommunications. InAs has a lattice mismatch of $\approx 7\%$ with GaAs; thin films of InGaAs can be deposited pseudo-

morphically but as the In content is increased the critical thickness falls, so that little more than a **ML** of InAs can be grown in this way. Thicker films will be relaxed by the formation of dislocations, limiting their usefulness for devices. The pseudomorphic **HEMT** (or **pHEMT**) replaces the GaAs channel of the conventional **HEMT** with a strained InGaAs channel in order to take advantage of the greater carrier confinement and superior electron transport properties. The maximum In content of the channel is limited by the need to prevent relaxation.

Under certain growth conditions InAs or InGaAs islands are formed spontaneously. It is generally accepted that the growth of InAs on GaAs (001) follows a version of the Stranski–Krastanov mode, which implies that following the deposition of ≈ 1.7 **ML** of InAs in a 2-D pseudomorphic form (sometimes referred to as the wetting layer), coherent 3-D growth is initiated by a very small increment (≤ 0.1 **ML**) of deposited material to relax the elastic strain introduced by the lattice mismatch. The **QDs** rapidly reach a saturation number density, which is both temperature- and In flux-dependent, with a comparatively narrow size (volume) distribution. The actual process is rather more complicated, not least as a result of alloying with the GaAs substrate, and is the subject of much current research [14.59].

These islands can be embedded in a layer of GaAs to form self-assembled quantum dots (**QDs**), which have become a topic of immense interest due to the potential application of **QDs** in a wide range of devices, especially lasers. The volume fraction of **QDs** in an active layer can be increased by building up a 3-D array; the strain field induced around each dot influences not only the inter-dot spacing but also the capping layer growth, so that subsequent layers of dots are aligned ([14.71] and references therein). **QD** lasers offer a route to long-wavelength emission from GaAs-based devices [14.116].

Group III Nitrides

The growth of Group III nitrides has been dominated by **MOVPE** since the demonstration of a high-brightness blue-emitting InGa_N-AlGa_N double heterostructure **LED** by *Nichia* [14.117] and the subsequent development of other optoelectronic devices, including laser diodes also emitting in the blue [14.118]. **MBE** has made a significant contribution to more fundamental studies and to the growth of nitrides for high-power and microwave devices. Once again the wide range of in situ diagnostic techniques available has been important.

For heteroepitaxial growth on the most commonly used substrates, sapphire and silicon carbide, several parameters strongly influence the quality of material

produced. These include substrate cleaning, initial nitridation, the nucleation and coalescence of islands involved in the low-temperature growth of a buffer layer, and subsequent annealing at a higher temperature. The polarity (nature of the outermost layer of atoms) of {0001}-oriented hexagonal structure films also has a crucial influence on material quality, but both N- or Ga-polarity can occur with **MBE** growth on sapphire substrates [14.119]. Under typical growth conditions with **MOVPE**, however, Ga-polarity material is exclusively produced.

Several of these problems can be resolved using GaN templates obtained by growing thick layers onto suitable substrates using **MOVPE** and then exploiting the advantages of **MBE** to produce the functional layer on the GaN template. These advantages include well-controlled layer-by-layer growth and lower growth temperatures than those used for **MOVPE**, so that InGa_N phase separation and In desorption are less problematic and precise quantum wells can be grown. No post-growth thermal annealing is required to activate the p-type dopant. In this way films have been produced with smooth surface morphology and high performance, although **MBE** was still limited to low-power **LEDs** until the recent demonstration of laser diodes [14.120].

In the use of active nitrogen from plasma sources, the III/V flux ratio at the substrate during growth is also a critical parameter. GaN layers grown with a low III/V flux ratio (N-stable growth) display a faceted surface morphology and a tilted columnar structure with a high density of stacking faults. Smooth surfaces are only obtained under Ga-rich conditions, where not only is there a dramatic reduction in surface roughness, but significant improvements in structural and electrical properties are also observed. This is, of course, the exact opposite of the growth of most III–V compounds, such as GaAs. In the case of nitrides, it is thought that Ga-rich conditions (close to the point where Ga droplets are formed) promote step flow growth, whereas N-stable growth promotes the nucleation of new islands. In contrast, growth from NH₃ is smoother under N-rich conditions [14.121].

Group III–V Nitrides

The “dilute nitrides” are III–V–N materials such as GaAs_N and GaInNAs, where the N concentration is $\leq 2\%$. Replacing a small fraction of As atoms with smaller N atoms reduces both the lattice constant and the bandgap. Adjusting the composition of GaInNAs allows the bandgap, band alignment, lattice constant and strain to be tailored in a material that can be lattice-

matched with GaAs [14.122]. This offers strong carrier confinement and thermal stability compared to InP-based devices operating at 1.3 μm and 1.55 μm , and allows GaAs VCSEL technology to be exploited at these wavelengths [14.123].

These materials are grown in a metastable regime at a low growth temperature because of the miscibility gap in the alloys, so a less stable precursor than NH_3 is needed. A nitrogen plasma source provides active N without the incorporation of hydrogen during growth associated with hydride sources, thus avoiding the deleterious formation of N–H bonds. Material with excellent crystallinity and strong PL at 1.3 μm can be obtained by optimizing growth conditions and using post-growth rapid thermal annealing [14.124]. A number of challenges remain, particularly in the higher N material required for longer wavelengths, including the limited solubility of N in GaAs and nonradiative defects caused by ion damage from the N plasma source. These challenges may be met by using GaInNAsSb; the addition of Sb significantly improves the epitaxial growth

and the material properties, and enhanced luminescence is obtained at wavelengths longer than 1.3 μm [14.125].

14.3.6 Conclusions

MBE, historically seen as centered on GaAs-based electronic devices, has broadened its scope dramatically in both materials and devices. In addition to the materials described above, MBE has been used to grow epitaxial films of a wide range of semiconductors, including other III–V materials such as InGaAsP/InP and GaAsSb/InAsSb; silicon and silicon/germanium; II–VI materials such as ZnSe; dilute magnetic semiconductors such as GaAs:Mn [14.126] and other magnetic materials. It has also been used for the growth of metals, including epitaxial contacts for devices, oxides [14.127] and organic films [14.128]. Two clear advantages possessed by MBE are the wide range of analytical techniques compatible with a UHV system and the precise control of growth to less than a monolayer, which give it unrivaled ability to grow quantum dots and other nanostructures.

15. Narrow-Bandgap II–VI Semiconductors: Growth

The field of narrow-bandgap II–VI semiconductors is dominated by the compound $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (CMT), although some Hg-based alternatives to this ternary have been suggested. The fact that CMT is still the preeminent infrared (IR) material stems, in part, from the fact that the material can be made to cover all IR regions of interest by varying the x value. In addition, the direct band transitions in this material result in large absorption coefficients, allowing quantum efficiencies to approach 100%. Long minority carrier lifetimes result in low thermal noise, allowing high-performance detectors to be made at the highest operating temperatures reported for infrared detectors of comparable wavelengths. This chapter covers the growth of CMT by various bulk growth techniques (used mainly for first-generation infrared detectors), by liquid phase epitaxy (used mainly for second-generation infrared detectors), and by metalorganic vapor phase and molecular beam epitaxies (used mainly for third-generation infrared detectors, including two-color and hyperspectral detectors). Growth on silicon substrates is also discussed.

The field of narrow-bandgap II–VI semiconductors is dominated by $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (CMT) (although some Hg-based alternatives to this ternary have been suggested and are discussed by Rogalski [15.1]). The reason that CMT is still the main infrared (IR) material is at least partially because this material can be made to cover all IR regions of interest by varying the value of x appropriately. This material also has direct band transitions that yield large absorption coefficients, allowing the quantum efficiency to approach 100% [15.2,3]. Furthermore, long minority carrier lifetimes result in low thermal noise allowing high-performance detectors to be made at the highest operating temperatures reported for infrared detectors of comparable wavelengths. These three major advantages all stem from the energy band structure of the material and they apply whatever device architecture is used. It has been shown that CMT is the third most stud-

ied semiconductor after silicon and gallium arsenide. This chapter covers the growth and characterization of CMT, mainly concentrating on the x region between 0.2 and 0.4 where the majority of applications are satisfied, and some of the Hg-based alternative ternary systems first described by Rogalski. The detectors made from these materials will be described in the chapter by Baker in this Handbook Chapt. 36.

In the first section the growth of CMT by various bulk techniques is reviewed. These include solid state recrystallization (SSR), Bridgman (plus ACRT, the accelerated crucible rotation technique), and the travelling heater method (THM). Despite the major advances made over the last three decades in the various epitaxial processes (liquid phase epitaxy, LPE, metalorganic vapor phase epitaxy, MOVPE, and molecular beam epitaxy, MBE), which are discussed in subsequent sections, bulk

techniques for CMT are still used for photoconductive devices and for large-size CdTe-based materials for CMT substrates (see Chapt. 16 on wide-bandgap II–VI compounds by Isshiki). CMT material grown by LPE is currently in production for large-area focal plane arrays (FPAs) for both terrestrial and space thermal imaging applications. More complex, fully doped heterostructures are being grown by MOVPE and MBE for both FPAs and novel nonequilibrium device structures. Both MOVPE

and MBE growth of device structures onto buffered silicon substrates is a topic of great interest currently, and this is briefly described.

For a fuller treatment of the topic matter in this chapter, plus further details of the characterization of CMT by various optical, electrical and structural means, the reader is referred to Chaps. 1 to 11 of [15.4], Sect. A of [15.5], Chaps. 1, 2, 10, 11, and 12 of [15.6], *Reine* [15.2], *Baker* [15.3], and Chapt. 7 of [15.7].

15.1 Bulk Growth Techniques

Despite the substantial progress that has taken place over the last three decades in various epitaxial growth techniques for CMT, bulk growth methods still play a key role when preparing device-quality material and producing substrates for these epitaxial techniques. A critical aspect of these techniques is the establishment of a thorough knowledge of the relevant phase equilibria, and a brief description of these phase diagrams for CMT is now given.

15.1.1 Phase Equilibria

The understanding of two types of equilibria is of critical importance. One is the solid compound in equilibrium with the gaseous phase (vapor growth) and the other is solid–liquid–gaseous equilibria (growth from liquid/melt). These phase equilibria also aid the understanding of post-growth heat treatments, either during cool-down to room temperature or during annealing processes used to adjust the stoichiometry, and hence the electrical properties of compounds. Solid–liquid–gaseous equilibria are described by three variables: temperature (T), pressure (p) and composition (x). It is, however, far easier to understand the interrelations between these parameters using two-dimensional (2-D) projections such as $T-x$, $p-T$ and $p-x$ plots.

A great deal of work has been carried out on the various phase equilibria ([15.5] contains reviews in this area). The liquidus and solidus lines in the pseudobinary HgTe–CdTe system are shown in Fig. 15.1. The wide separation between the liquidus and solidus, leading to marked segregation between the constituent binaries, CdTe and HgTe, was instrumental in the development of all the bulk growth techniques applied to this system. In addition to the solidus–liquidus separation, high Hg partial pressures are also influential during growth and post-growth heat treatments. A full appreciation of the

Fig. 15.1 $T-x$ phase diagram for the pseudo-binary CdTe–HgTe. (After [15.5])

$p_{\text{Hg}}-T$ diagram, shown in Fig. 15.2, is therefore essential. The curves are the partial pressures of Hg along boundaries for solid solutions of composition x where the solid solution is in equilibrium with another condensed phase as well as the vapor phase. For $x = 0.1$ and $10^3/T = 1.3 \text{ K}^{-1}$, CMT exists for Hg pressures between ≈ 0.1 (Te-saturated) and ≈ 7 (Hg-saturated) atm. Even at $x = 0.95$ and Te-saturated conditions, Hg is the predominant vapor species. It should also be noted that no solid solution contains exactly 0.5 atomic fraction Te. These features are highly significant for controlling the native defect concentrations and hence electrical properties in CMT.

15.1.2 Crystal Growth

Growth from the melt has constituted the vast majority of work on bulk growth of CMT. CMT grown by

several bulk methods is still in use, particularly for photoconductive detectors. Several historical reviews have been published [15.5, 8–10]. *Micklethwaite* [15.8] and *Kruse* [15.9] gave detailed discussions on the growth techniques and material characterization prior to 1980. Many techniques were tried, but three prime techniques survived these early attempts – **SSR**, Bridgman and **THM** – some of which are still in production, such as **SSR** in Germany and Bridgman in the UK. *Tennant et al.* [15.11] provided an authoritative view of the then current major issues in growth techniques. They concluded that the electrical performance had only recently been matched by **LPE** but pointed to the major drawbacks in bulk material of structural defects and size limitations for use in second-generation infrared detectors, such as focal plane arrays (**FPAs**).

Solid State Recrystallization (SSR)

This technique is used for ternary systems where there is a wide separation between solidus and liquidus, such as CMT. Other names that have been used for this process are quench anneal (**QA**) and cast recrystallize anneal (**CRA**). The term anneal is used in the first case to define a high-temperature grain-growth process, while in **CRA** it is a low-temperature process to adjust stoichiometry. In the basic technique, pure elements are

loaded into a cleaned silica ampoule and the charge is melted and rocked to ensure complete mixing. Charges are then normally quenched rapidly, into air or oil, to room temperature in the vertical orientation. This produces a dendritic structure that is reduced/removed by the recrystallization step that occurs at temperatures just below the melting point for many days. Grain growth occurs and microinhomogeneities in composition are removed. Care must be taken in the quenching stage to avoid pipes/voids that cannot be removed by the recrystallization step.

Alternatives to the basic **SSR** process have included ‘slush’ growth [15.12], high-pressure growth [15.13], incremental quenching [15.14] and horizontal casting [15.15]. In the ‘slush’ process, an initial homogenous charge is prepared and then held across the liquidus–solidus gap with the lower end solid and the upper end liquid. High-pressure growth (30 atm He gas) was used in an attempt to reduce structural defects. The ‘slush’ technique was used in production in the USA, while the incremental quenching technique has been used to provide large-diameter feed material for **THM** growth by *Colombo et al.* [15.16]. Other developments were made in the basic process (e.g. [15.17, 18]) but details available in the open literature are sketchy, due to proprietary constraints. *Tregilgas* [15.19] has given a detailed review of the **SSR** process.

Fig. 15.2 p – T diagram for $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (CMT). (After [15.5])

Bridgman (plus ACRT)

In the standard Bridgman process, elemental Cd, Hg and Te are loaded into a clean silica ampoule, homogenized by melting/rocking, and then frozen slowly from one end in a vertical system (Fig. 15.3, [15.20]) to produce a large-grained ingot [15.21]. There is marked segregation of CdTe with respect to HgTe (due to the wide gap between the solidus and liquidus) in the axial direction, but this leads to an advantage of the Bridgman process over other techniques: that material in both the main ranges of interest (3–5 and 8–12 μm : $x = 0.3$ and 0.2, respectively) is produced in a single run. The accelerated crucible rotation technique (**ACRT**) in which the melt is subjected to periodic acceleration/deceleration provided a means of stirring melts contained in sealed, pressurized ampoules. However, it has been recently suggested that **ACRT** does not automatically promote melt mixing [15.22]. They suggest that the balance of two time-dependent fluid dynamics phenomena decides whether mixing is promoted or not.

The first report of **ACRT** in CMT Bridgman growth was given in [15.23]. These effects were developed and reviewed in [15.5, 21]. Crystals were produced up to

Fig. 15.3 Schematic of Bridgman growth kit for use with Hg-based compounds. (After [15.20])

20 mm in diameter and with x values of up to 0.6 in the tip regions of some crystals. Currently in this author's laboratory, crystals up to 21 mm in diameter and 200 mm in length weighing 0.5 kg are in routine production. Extensions to the basic ACRT process are enabling material of up to $x \approx 0.7$ to be produced in the first-to-freeze regions of crystals. These near-IR slices are highly transmissive and show a high degree of compositional uniformity ($\Delta x \approx 0.005$), see [15.24]. The use of ACRT produced material that enabled the fabrication of small two-dimensional arrays of photodiodes; this material was also used to demonstrate nonequilibrium detector operation and in the production of SPRITE detectors (Chapt. 11 of [15.6]).

Traveling Heater Method (THM)

Triboulet [15.25] (and his coworkers) developed this technique for CMT where diameters of up to 40 mm were accomplished and x values of up to 0.7 [15.26] for optical communication devices. Durand et al. [15.27] employed seeds to produce large oriented crystals, an advantage of this technique over other bulk methods. Gille et al. [15.28] adopted a slightly different approach. A pre-THM step was used to produce a quenched Te-rich

(53–60%) CMT melt. A first THM run then provided the source ingot, after removal of the tip and tail sections, for the final THM run. The entire growth procedure took several months but gave uniform material. This group also used rotation in the horizontal growth by THM with some success [15.29]. Two groups also applied ACRT to THM and obtained enhanced material properties [15.30,31].

15.1.3 Material Characterization

Compositional uniformity can be expressed in both the axial and the radial directions as $\Delta A(x)$ and $\Delta R(x)$, although the combination of the two clearly determines the yield of useful material. Assessment is normally by Fourier transform infrared (FTIR) spectrometry. The recrystallization process (in SSR) improves $\Delta A(x)$ from ± 0.05 to ± 0.02 [15.9] and removes the microinhomogeneity in x in both directions [15.32]. Independent control of axial and radial variations was claimed by Nelson et al. [15.33] to achieve ± 0.002 over 95% of slices up to 25 mm in diameter. Colombo et al. [15.14] quote $\Delta R(x)$ values of 0.005–0.01 in incremental-quenched material. Su et al. [15.34] report ± 0.008 for $\Delta A(x)$ and $\Delta R(x)$ in vertically cast material but better in horizontally cast material. Galazka [15.35] showed that reduced gravity gives smaller $\Delta R(x)$, and they also noted that constitutional supercooling at the first-to-freeze end is also reduced and the growth is diffusion-limited. The 'slush' process [15.8] produces $\Delta R(x)$ of ± 0.005 but only over the region of axially uniform material ≈ 3 mm in length.

Bartlett et al. [15.36] grew SSR and Bridgman crystals over a wide range of growth rates and concluded that $\Delta R(x)$ was due to the combination of a concave (to the melt) growth interface and density-driven convective flow within a boundary layer close to the interface. This, added to the normal segregation of the low melting point HgTe to the center of the concave interface, led to the observed variation. It was also concluded that crystals with simultaneous small $\Delta A(x)$ and $\Delta R(x)$ were not possible; slow growth gave low $\Delta R(x)$ while fast growth minimized $\Delta A(x)$. In Bridgman material grown with ACRT, an 80 mm length at $x = 0.21$ with both $\Delta A(x)$ and $\Delta R(x)$ within ± 0.002 was reported by Capper [15.21]. This was linked to a flat interface produced by strong Ekman flow in the interface region, although all Bridgman crystals have concave interfaces next to the ampoule walls [15.21]. A 20 mm-diameter ACRT crystal was grown that exhibited $\Delta R(x) = \pm 0.003$ at $x = 0.22$ [15.21].

Triboulet et al. [15.10] quoted values of ± 0.02 (over 3 cm at $x = 0.2$) and ± 0.002 for $\Delta A(x)$ and $\Delta R(x)$, respectively, for **THM** growth at 0.1 mm/h. Corresponding figures from *Colombo et al.* [15.16] for incremental-quenched starting material and a similar growth rate of 2 mm/d were ± 0.01 and ± 0.005 . For the very slow grown material produced by *Gille et al.* [15.28], variations in composition were within experimental error for $\Delta R(x)$ while $\Delta A(x)$ was ± 0.005 . *Royer et al.* [15.30] obtained improved radial uniformity with the addition of **ACRT** to **THM**, but in the work of *Bloedner and Gille* [15.31] both $\Delta A(x)$ and $\Delta R(x)$ were only as good as non-**ACRT** crystals.

With regard to electrical properties, as-grown materials from **SSR**, **ACRT** Bridgman (with $x < 0.3$) and **THM** are highly p-type in nature, believed to be due to metal vacancies. These types of materials can all be annealed at low temperatures, in the presence of Hg, to low n-type levels, indicating that the p-type character is due to metal vacancies. By contrast, Bridgman material is n-type as-grown [15.21] and the residual impurity donor level is found to be $< 5 \times 10^{14} \text{ cm}^{-3}$. *Higgins et al.* [15.18] have shown that n-type carrier concentrations can be $< 10^{14} \text{ cm}^{-3}$ at $x \approx 0.2$ in melt-grown material. A great deal of work has been done on the annealing behavior of **SSR** material, see *Tregilgas* [15.19]. n-type levels of $2 \times 10^{14} \text{ cm}^{-3}$ after Hg annealing $x = 0.2$ and higher- x material were reported by *Nguyen Duy et al.* [15.26], while *Colombo et al.* [15.16] quote $4 \times 10^{14} \text{ cm}^{-3}$. *Durand et al.* [15.37] note that **THM** growth at 600 °C results in p-type behavior, but growth at 700 °C gives n-type material. In this author's laboratory, current 20 mm-diameter **ACRT** material has reached mid- 10^{13} cm^{-3} levels with high mobility after a normal low-temperature Hg anneal step. This is thought to reflect the improvements made in the purity of starting elements over the recent years. The basic p to n conversion process [15.19] has recently been extended by *Capper et al.* [15.38] to produce analytical expressions that can account for the temperature, donor level and composition dependencies of the junction depth.

High minority n-type carrier lifetimes have been reported in all three types of material. *Kinch* [15.39] noted values $> 1 \mu\text{s}$ (at 77 K) in $x = 0.2$ **SSR** crystals, while *Triboulet et al.* [15.10] quote $3 \mu\text{s}$ in **THM** material. *Pratt and coworkers* [15.40,41] found high lifetimes, up to $8 \mu\text{s}$ in $x = 0.23$ Bridgman and **ACRT** material with n-type levels of $1\text{--}6 \times 10^{14} \text{ cm}^{-3}$, and up to $30 \mu\text{s}$ for equivalent $x = 0.3$ material (192 K).

In terms of extrinsic doping, most elements are electrically active in accordance with their position in the

Periodic Table. This is true in **SSR** material for Group V and VII elements only after a high-temperature treatment, and is linked to the stoichiometry level at the growth temperature (in other words, those elements that substitute on Te lattice sites have to be forced onto the correct sites in Te-rich material). Group I and III elements are acceptors and donors, respectively, on the metal sites. There is evidence that some Group I elements can migrate at low temperatures to grain boundaries or to the surface of samples [15.21]. In **ACRT** crystals, Groups I and III are acceptors and donors, respectively, on the metal sites, as they are in Bridgman, with the exception of Au [15.21]. Groups V and VII are inactive dopants in those portions of **ACRT** crystals that are Te-rich as-grown ($x < 0.3$), but are active dopants for $x > 0.3$ where metal-rich conditions prevail, as found in Bridgman material. In doped material, grown by either standard Bridgman or **ACRT**, acceptor ionization energies were found to be lower than undoped counterparts [15.21]. Segregation of impurities in **SSR** is very limited due to the initial fast quench step. By contrast, Bridgman and **THM** benefit from marked segregation of impurities due to their relatively slow growth rate. Impurity segregation behavior was affected by **ACRT** [15.21], in general, segregation coefficients decrease in **ACRT** crystals, when compared to standard Bridgman. This segregation leads to very low levels of impurities in both **THM** [15.25] and Bridgman/**ACRT** material [15.42].

Vere [15.43] has reviewed structural properties and noted grains, subgrains, dislocations, Te precipitates and impurities on dislocations as major problems. Grain boundaries act as recombination centers and generate noise and dark current in devices. Subgrain sizes cover 50–500 μm in both **SSR** and Bridgman material. *Williams and Vere* [15.44] showed how a recrystallization step at high pressure and temperatures of $> 600^\circ\text{C}$ coalesces subgrains and eventually eliminates them. Tellurium precipitation was extensively studied [15.44,45] and was summarized in [15.44]. Precipitates were found to nucleate on dislocations during the quench from the recrystallization step but a 300 °C anneal dissolves the precipitates, generating dislocation loops that climb and lead to dislocation multiplication.

Quenching studies in Bridgman/**ACRT** crystals grown in flat-based ampoules [15.21] revealed not only a flat growth interface but also that the slow-grown material produced prior to quenching was single crystal. This demonstrated the power of Ekman stirring and the importance of initiating the growth of a single crystal grain. In Bridgman material, which is close

to stoichiometric (Te excess < 1%), little Te precipitation occurs. Above this limit, precipitates/inclusions of 0.1–0.5 mm in size are seen. Recent work in this author's laboratory [15.24] has demonstrated flat solid–liquid interfaces in the $x \approx 0.21$ region of 20 mm-diameter ACRT crystals, mirroring the high level of compositional uniformity in these crystals.

Triboulet et al. [15.10] found no Te precipitates in their THM material, despite using a Te zone. Several groups [15.14, 46] noted an increase in dislocation density and in rocking curve widths on moving from the center to the edge of THM crystals. The addition of ACRT to the THM process led to increased growth rates with no detriment to the Te precipitation or grain structure.

We have recently [15.24, 47] extended our ACRT growth process to produce high- x material for various near-IR applications. This necessitated improving the ampoule sealing procedure to manage the higher pressures caused by the higher growth temperatures. Assessment techniques were extended beyond the normal FTIR wavelength characterization to include imaging of defects using a mid-IR camera system.

To summarize, the two main problems with all bulk material are the limitation on size – only THM has reproducibly produced material above 20 mm in diameter – and the fact that it is rarely completely single-crystal in nature. These two limitations led to the drive in the late 1970s and early 1980s to develop various epitaxial growth techniques.

15.2 Liquid-Phase Epitaxy (LPE)

The process of LPE has emerged as the predominant materials growth technology for the fabrication of second-generation CMT focal plane arrays (FPAs). Material can now be routinely grown for high-performance photoconductive, photovoltaic, and laser-detector devices over the entire 2–18 μm spectral region. This is manifested by increased size (over bulk material), enabling large-array formats to be made; reduced cycle time; better material characteristics in terms of composition uniformity, crystal quality, and electrical properties, making the material no longer the limiting factor in FPAs; and the realization of some advanced device structures, either to simplify the FPA design (back-side-illuminated detectors) or to enhance detector performance (double-layer heterostructures).

Two completely different technical approaches have been pursued: growth from Te solutions and growth from Hg solutions. One major advantage of the Hg-solution

technology is its ability to produce layers of excellent surface morphology due to the ease of melt decanting. Two additional unique characteristics, essential for the fabrication of high-performance double-layer heterojunction (DLHJ) detectors by LPE, are low liquidus temperature (< 400 °C), which makes growth of the cap layer feasible, and ease of incorporating both p-type and n-type temperature-stable impurity dopants, such as As, Sb and In, during growth. While layers grown from Hg-rich solutions are easily doped with Group VB elements with high solubility [15.48], layers grown from tellurium-rich solutions are not. Group IIIB elements, in particular indium, are easily incorporated from both solutions.

A number of LPE approaches have been used to grow both thin and thick films. The principal LPE techniques used are tipping, dipping and sliding boat techniques. A schematic diagram of these three processes is shown in Fig. 15.4. The tipping and dipping techniques have been

Fig. 15.4 Dipping, sliding boat and tipping LPE arrangements

implemented by using both tellurium- and mercury-rich solutions, whereas only tellurium-rich solutions have been used with the sliding boat. Both dipping and sliding boat Te-rich techniques are still in widespread use.

Extensive experimental phase diagram and thermodynamic data have been critically reviewed, along with the results calculated by the associated solution model [15.49]. As in bulk growth, full knowledge of the solid–liquid phase relation is essential for proper use of solution-growth processes. In addition, the solid–vapor and liquid–vapor phase relations are of practical importance, especially in view of the high Hg pressure in the growth process and the effect of the vapor of constituent components upon post-growth annealing and the consequent electrical properties. *Astles* [15.50] reviewed the experimental data on Te-rich LPE growth at 460 to 550 °C.

15.2.1 Hg-Rich Growth

For CMT growth from Hg-rich melts, the design and operation of a system is dominated by the consideration of the high vapor pressure of Hg, which comprises $\geq 90\%$ of the growth solution. A secondary but related factor is the requirement to minimize melt composition variation during and between growths due to solvent or solute loss. These factors led to the evolution of a vertical high-pressure furnace design with a cooled reflux region. The furnace has to provide a controllable, uniform and stable thermal source for the melt vessel, which has to be capable of maintaining at least 550 °C continuously. The cylindrical melt vessel consists of a high-strength stainless steel chamber lined with quartz. Such systems are capable of containing about 10–20 kg of melt at 550 °C for several years with no degradation in melt integrity or purity.

The system must be pressurized and leak-free to keep the Hg-rich melt from boiling or oxidizing at temperatures above 360 °C. Typical pressures range up to 200 psi and the pressurization gas may be high-purity H_2 or a less explosive reducing gas mixture containing H_2 . The melts are always kept saturated and are maintained near to the growth temperature and pressure between successive runs. The prepared substrates are introduced into the melt through a transfer chamber or air lock. A high-purity graphite paddle with externally actuated shutters holds the substrates. The paddle with the shutters closed is not gas-tight but protects the substrates from undue exposure to Hg vapor/droplets, or other condensing melt components. The paddle assembly can be lowered into the melt and rotated to stir it.

In normal operation, the high-purity melt components are introduced into the clean melt vessel at room temperature and the system is sealed, evacuated and pressurized. The temperature of the furnace is raised above the predicted melting point and held constant until all of the solute dissolves. The amount of material removed from the melt during each growth run is relatively insignificant. Optimum layer smoothness occurs on polished lattice-matched CdZnTe substrates oriented close to the $\langle 111 \rangle$ plane. Growth begins by lowering the paddle plus substrates into the melt and allowing thermal equilibrium to be reached while stirring. A programmed ramp then reduces the melt temperature to the required level, at which point the shutters are opened and the substrates are exposed to the melt. The growth rate and layer thickness are determined mainly by the exposure temperature relative to the saturation point and the total growth range. The composition of the layer and its variation are determined mainly by the melt composition and its thermal uniformity. Large melts allow the production of layer areas of up to 30 cm² with excellent compositional and thickness uniformity, and allow dopant impurities to be accurately weighed for incorporation into layers and to maintain stable electrical characteristics over a long period of time. Four layers with a total area of 120 cm² can be grown in a single run [15.51]. *Norton et al.* [15.52] have also scaled-up for the growth of cap layers from Hg-rich solutions, with each reactor capable of growth on four 24 cm² base layers per run.

15.2.2 Te-Rich Growth

A number of problems encountered with bulk crystal growth techniques are solved using CMT growth from tellurium-rich solution. The most important of these is the reduction of the Hg vapor pressure over the liquid by almost three orders of magnitude at the growth temperature. Growth from Te-rich solutions is used in three embodiments: dipping, tipping and sliding boat technologies (Fig. 15.4). While the tipping process may be used for low-cost approaches, it is not as widely used as the sliding boat and the dipping techniques. A comparison of the three techniques is shown in Table 15.1.

Current dipping reactors are capable of growing in excess of 60 cm² per growth run and are kept at temperature for long periods, > 6 months. Melts, on the other hand, last a very long time, > 5 years. A sensor-based reactor capable of growing CMT thick layers at relatively high production volumes and with excellent

Table 15.1 Comparison of three LPE growth techniques

LPE growth technique	Advantages	Disadvantages
Sliding boat	Thickness control Large area Double layers	Thick layers difficult to grow Substrate thickness/planarity control High cost
Tipping	Thickness control Lowest investment for experimental investigation Closed system/good p_{Hg} control	High cost Scale up
Dipping	Thick layer growth High throughput Low cost Large/flexible area	Thin-layer thickness control Double layers

Fig. 15.5 Schematic diagram of a dipping LPE reactor showing the Te-rich melt, the mercury reservoir and positions of the sensors

reproducibility was described by Westphal et al. [15.53], Fig. 15.5. The reactors utilize resistance temperature devices (RTDs) for temperature control, a UV-vis spec-

trometer to measure the mercury partial pressure, and a video camera to aid in the observation of the liquidus temperature. The RTDs were used to control the temperature within a maximum range of $\pm 0.005^\circ\text{C}$ at a temperature of $\approx 480^\circ\text{C}$. The melts are about 4 kg with a liquidus temperature of $\approx 480^\circ\text{C}$ for a solid CMT composition of $x = 0.225$. Accurate mercury vapor pressure control ensures constant liquidus and thus constant liquid composition.

Layers produced from Te-rich solutions are usually grown by isothermal supersaturation, programmed cooling techniques, or a combination of both. The details of the mass transport of Hg-Cd-Te solutions during LPE growth were presented by Shaw [15.54]. He predicted that isothermal growth of thin layers from supersaturated solutions would yield layers with uniform composition but that the growth rate would change during growth. While the growth rate is more uniform for layers grown by the programmed cooling technique, the composition gradient is higher.

The dipping growth process comprises: 1) mixing, 2) liquidus measurement, 3) meltback, and 4) growth. Because of the relatively large melt, stirring is required to mix the solution. The choice of growth method depends on the desired properties of the films. Typically, isothermal supersaturation is preferred when growing thin layers, whereas programmed cooling or a combination of both is used for thicker films. Colombo et al. [15.55] used a melt-tracking technique to control the composition of the solid.

Sliding-boat LPE normally consists of a graphite boat with a recess in the base to hold the substrate wafer and a movable block with wells that contain the

LPE solution and that allows the solution to be brought into contact with the substrate and then wiped off after growth. The main advantages of the technique are the efficient use of solution and the possibility of growing multilayers. The main disadvantages are the need for careful machining of the boat components in order to obtain efficient removal of the solution after growth and the need for precisely sized substrate wafers to fit into the recess in the boat. The sliding boat growth process has several variants, but essentially a polished substrate is placed into the well of a graphite slider and the Te-rich solution is placed into a well in the body of the graphite boat above the substrate and displaced horizontally from it. Normally, a separate well contains the HgTe charge to provide the Hg vapor pressure needed during growth and during cool-down to control the stoichiometry. The boat is then loaded into a silica tube that can be flushed with nitrogen/argon prior to the introduction of H_2 for the growth phase. The furnace surrounding the work tube is slid over the boat, and the temperature is increased to 10–20°C above the relevant liquidus. At that point, a slow temperature ramp (2–3°C/h) is initiated, and when the temperature is close to the liquidus of the melt the substrate is slid under the melt and growth commences. After the required thickness of CMT has been deposited (typical growth rates are 9–10 $\mu\text{m/h}$), the substrate is withdrawn and the temperature is decreased to an annealing temperature (to fix the p-type level in the as-grown material) before being reduced rapidly to room temperature. Layer thicknesses of 25–30 μm are normally produced for loop-hole diode applications [15.56].

15.2.3 Material Characteristics

Good composition uniformity, both laterally and in depth, is essential in order to obtain the required uniform device performance. Growth parameters that need to be optimized in Hg-rich LPE include the degree of supercooling and mixing of the melt, the geometrical configuration of the growth system, the melt size and the phase diagram. The standard deviation of the cut-off wavelength, for 12-spot measurements by Fourier transform infrared (FTIR) transmission at 80 K across a 30 cm^2 LWIR layer, is reported as 0.047.

Composition control and the uniformity of layers grown by dipping Te-rich LPE is one of the strengths of this process. The cut-off wavelength reproducibility is typically $10.05 \pm 0.18 \mu\text{m}$. Dipping Te-rich LPE is mainly used to grow thick films, about 100 μm , hence thickness control is not one of its advantages. Thickness

control is about $\pm 15\%$ for layers of $< 20 \mu\text{m}$ due to the relatively large amount of solidified material.

For Te-rich sliding-boat LPE, layers of $\approx 30 \mu\text{m}$ thickness can show wavelength uniformity at room temperature of $6.5 \pm 0.05 \mu\text{m}$ over 90% of the area of $20 \times 30 \text{ mm}$ layers [15.57].

The ease of decanting the Hg-rich melt after layer growth results in smooth and specular surface morphology if a precisely oriented, lattice-matched CdZnTe substrate is used. Epitaxial growth reproduces the substructure of the substrate, especially in the case of homoepitaxy.

The dislocation density of LPE CMT and its effects on device characteristics have received much attention [15.58, 59]. The dislocation density is dominated mainly by the dislocations of the underlying substrate [15.60]. For layers grown on substrates with $\text{ZnTe} \approx 3-4\%$, the dislocations are present only in the interface region and the dislocation density is close to that of the substrate. For layers grown on substrates with $\text{ZnTe} > 4.25\%$, dislocation generation is observed within a region of high lattice parameter gradient. The same variation of dislocation density with depth is seen for sliding-boat LPE material [15.56] (typical values are $3-7 \times 10^4 \text{ cm}^{-2}$).

For the production of heterostructure detectors with CMT epitaxial layers, it is essential that proper impurity dopants be incorporated during growth to form well-behaved and stable p–n junctions. An ideal impurity dopant should have low vapor pressure, low diffusivity, and a small impurity ionization energy. Group V and Group III dopants – As and Sb for p-type and In for n-type – are the dopants of choice. Hg-rich melts can be readily doped to produce n- and p-type layers; the solubilities of most of the useful dopants are significantly higher than in Te-rich solutions, most notably for Group V dopants, which are among the most difficult to incorporate into CMT.

Accurate determinations of dopant concentration in the solid involve the use of Hall effect measurements and secondary ion mass spectrometry (SIMS) concentration profiles. Measurements on the same sample by the two techniques are required to unequivocally substantiate the electrical activity of impurity dopants. The ease of incorporating Group I and Group III dopants into CMT, irrespective of non-stoichiometry, has been confirmed experimentally [15.5, 61].

The excess carrier lifetime is one of the most important material characteristics of CMT since it governs the device performance and frequency response. The objective is to routinely produce material with a lifetime that

is limited by Auger processes, or by the radiative process in the case of the medium-wavelength infrared (MWIR) and short-wavelength infrared (SWIR) material [15.62]. It has been reported that intentionally impurity-doped LPE CMT material grown from As-doped Hg-rich melts can be obtained with relatively high minority carrier lifetimes [15.63]. The 77 K lifetimes of As-doped MWIR ($x = 0.3$) CMT layers are significantly higher than those of undoped bulk CMT and are within a factor of two of theoretical radiative lifetimes. Various annealing schedules have been proposed recently [15.38] that may lead to a reduction in Shockley–Read traps with a consequent increase in lifetime, even in undoped material. Lifetimes in In-doped MWIR CMT were also found to exhibit an inverse linear dependence on the doping concentration [15.63], with $N_d\tau$ products similar to $N_a\tau$ products observed for the As-doped material. The lifetimes of LWIR In-doped LPE material are typically limited by the Auger process at doping levels above 10^{15} cm^{-3} .

The first heterojunction detectors were formed in material grown by Hg-rich LPE [15.64]. For double-layer heterojunctions (DLHJ), a second LPE (cap) layer is grown over the first (base) layer. With dopant types and layer composition controlled by the LPE growth process, this approach offers great flexibility (p-on-n or n-on-p) in junction type and in utilizing heterojunction formation between the cap and absorbing base layers to optimize detector performance. The key step in the process is to grow the cap layer doped with slow-diffusing impurities,

In for an n-type cap layer, and As or Sb for a p-type cap layer.

For future large-area FPAs, Si-based substrates are being developed as a replacement for bulk CdZnTe substrates. This effort is directed at improvements in substrate size, strength, cost and reliability of hybrid FPAs, particularly during temperature cycling. These alternative substrates, which consist of epitaxial layers of CdZnTe or CdTe on GaAs/Si wafers [15.65] or directly onto Si wafers [15.66], are particularly advantageous for the production of large arrays. High-quality epitaxial CMT has been successfully grown on the Si-based substrates by the Hg-melt LPE technology for the fabrication of p-on-n DLHJ detectors. The first high-performance 128×128 MWIR and LWIR arrays were demonstrated by Johnson et al. [15.67]. MWIR arrays as large as 512×512 and 1024×1024 have also been produced [15.68]. A bias-selectable two-color (LWIR/MWIR) detector structure was first fabricated by growing three LPE layers from Hg-rich melts in sequence on a bulk CdZnTe substrate [15.68]. The structure forms an n-p-n triple-layer graded heterojunction (TLHJ) with two p-n junctions, one for each spectral band (color).

Destefanis et al. [15.69] have recently described their work on large-area and long linear FPAs based on Te-rich sliding-boat LPE material. Using a $15 \mu\text{m}$ pitch they were able to produce 1000×1000 MW arrays of photodiodes and 1500×2 MW and LW long linear arrays.

15.3 Metalorganic Vapor Phase Epitaxy (MOVPE)

Metalorganic vapor phase epitaxy (MOVPE) of CMT is dominated by the relatively high vapor pressures of mercury that are needed to maintain equilibrium over the growing film. This arises from the instability of HgTe compared with CdTe, and requires much lower growth temperatures than are usual for more stable compounds. The MOVPE process was developed as a vapor phase method that would provide sufficient control over growth parameters at temperatures below 400°C , the main advantage being that the elements (although not mercury) can be transported at room temperature as volatile organometallics and react in the hot gas stream above the substrate or catalytically on the substrate surface. The first mercury chalcogenide growth by MOVPE [15.70,71] was followed by intense research activity that has brought the technology to its current state of maturity.

Although the MOVPE reaction cell conditions are far from equilibrium, an appreciation of the vapor–solid equilibrium can determine the minimum conditions needed for growth. This is particularly important with the mercury chalcogenides, where the relatively weak bonding of mercury causes a higher equilibrium vapor pressure. The equilibrium pressures of the component elements are linked and there is a range of pressures over which the solid remains in equilibrium as a single phase. At MOVPE growth temperatures, the pressure can vary by three orders of magnitude and remain in equilibrium with a single phase of HgTe. However, the Te_2 partial pressure varies across the phase field in the opposite sense to the Hg partial pressure.

The maintenance of vapor pressure equilibrium within the reactor cell does not automatically lead to the growth of an epilayer, but it does enable us to elimi-

nate conditions that would not be suitable. For example, the supply of Hg to the substrate for growth at 400 °C must be greater than the minimum equilibrium pressure of 10^{-2} bar. This pressure is higher than would be conveniently delivered from a mercury organometallic source that would typically be less than 10^{-3} bar. All narrow-gap II–VI epilayers, except for a few examples of very low temperature growth, have used a heated mercury source that is capable of delivering the required partial pressure.

The criteria for precursors that are generally applicable to MOVPE are volatility, pyrolysis temperature, stability and volatility of organic products and purity. The latter depends on synthesis and purification routes for the precursors, but techniques such as adduct purification of the Group II organometallics have made a major contribution to epilayer purity. A good review of this topic is given by Jones [15.72].

The precise control over layer properties that is required for uniform detector arrays and tuning of the response wavelength band can only be achieved if the cadmium concentration is controlled to better than 1%. Improvements in reactor design, growth techniques (such as IMP – the interdiffused multi-layer process), choice of precursors and operating conditions have all contributed to successful targeting of the composition and thickness. However, these conditions are difficult to achieve on a run-to-run basis due to drifts in calibration, and they will require additional levels of control. Recent developments with in situ monitoring

have been instrumental to gaining a better understanding of this technology and to reducing variance in epilayer properties. This has been achieved with better system monitoring to measure organometallic concentration and epilayer monitoring with laser reflectometry or ellipsometry [15.73].

A typical example of a horizontal reactor cell with an internal mercury source is shown in Fig. 15.6. The reactor cell wall temperature is also determined by the thermodynamics, which requires a minimum temperature in order to avoid condensation of mercury, and these requirements can be simply determined from the phase diagram. The organometallic supply shows the DMCD injected beyond the Hg source, which is the most common practice used to avoid reaction in the Hg zone.

Much of the work on precursors has been concerned with the thermal stability of the tellurium source, as this limits the growth temperature. From thermodynamic considerations, it would be desirable to grow at low temperature (below 400 °C) where the requirement on Hg equilibrium pressure will be lower. The initial demonstration of growth using MOVPE was with diethyl telluride (DET_e), which requires a temperature above 400 °C for efficient pyrolysis [15.71].

Despite some high hopes of reducing the growth temperature to 200 °C, where the required equilibrium mercury vapor pressure would be as low as 10^{-7} bar, the most successful tellurium source has been diisopropyltelluride (DIPT_e), which is used for growth between 350 and 400 °C. In practice, the DiPT_e bubbler is held

Fig. 15.6 Horizontal reactor cell with internal mercury source and gas supply suitable for the growth of $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ alloy. (After S.J.C. Irvine, in [15.4])

at a temperature above ambient (up to 30°C) and the lines to the reactor are heated to avoid condensation of the precursor in the feed lines. Care must be taken, however, not to overheat the lines and cause premature pyrolysis.

Although most of the development of precursors in narrow gap II–VI semiconductors has been concerned with the tellurium source, there have been some important developments with the Group II sources. The cadmium source dimethyl cadmium (**DMCd**) appears to work well down to 250°C, although this probably relies on reaction chemistry with the tellurium source.

Unlike **MOVPE** growth of other II–VI and III–V semiconductors, the growth of an alloy in narrow-gap II–VIs can be achieved by one of two alternative processes, direct alloy growth (**DAG**) and the interdiffused multilayer process (**IMP**). The requirement on alloy uniformity is critical, because this will determine the cut-on wavelength of a detector, and for focal plane arrays there needs to be uniformity of cut-on wavelength across the array. The **DAG** approach suffers from disadvantages in the thermodynamics and reaction chemistry in that the reaction rate of the tellurium precursor is very different when growing the mercury-containing binary compared with Zn, Cd, or Mn. This leads to a preferential depletion of the non-Hg Group II species as the gas flow passes over the substrate, and consequent compositional changes in the flow direction.

The interdiffused multilayer process [15.75] separates the growth of HgTe and CdTe so that the growth of the binaries can be independently optimized. The procedure entails the growth of alternate layers of HgTe and CdTe that interdiffuse during the time of growth to give a homogeneous epitaxial layer. The **IMP** approach relies on the very high interdiffusion coefficients in the CMT pseudobinary [15.38], and the basic principles are as follows:

1. Interdiffusion must occur at the growth temperature, and a nominal time at the end of growth for the last periods to interdiffuse must be allowed.
2. There should be no residual compositional or structural modulation attributable to the **IMP** oscillations.
3. Interdiffusion at heterointerfaces should be no greater than for direct alloy growth (**DAG**) at that temperature.
4. Flow velocity is adjusted between the two binary growths in order to optimize growth uniformity.

The alloy composition is fixed by adjusting the times for growth of the HgTe and CdTe **IMP** layers. Figure 15.7 shows the uniformity of wavelength over a 3-inch-diameter **MOVPE** layer grown on a GaAs:Si substrate [15.74]. 2-D contour maps of the cut-off wavelength of 3–5 μm wavelength slices (contour steps = 0.1 μm) showed that without rotation

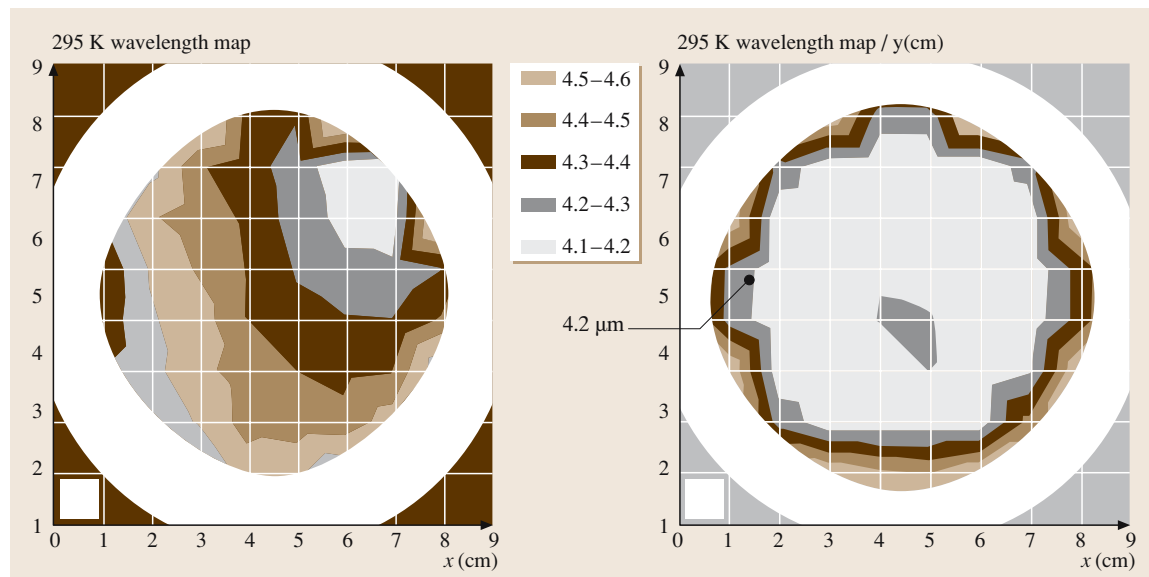

Fig. 15.7 Uniformity of wavelength over a three-inch-diameter **MOVPE** layer grown on a GaAs:Si substrate. (After [15.74])

(Fig. 15.7a) there is a gradual decrease in composition from upstream to downstream such that the compositional uniformity was within ± 0.022 in x . The thickness uniformity was typically $\pm 5-6\%$. However, by introducing substrate rotation, the uniformity improved dramatically such that, to within a few millimeters of the wafer edge, the composition was uniform to within ± 0.004 (Fig. 15.7b). The thickness uniformity also improved to within $\pm 2-3\%$. This was compatible with the production of twelve sites of large-format 2-D arrays (640×512 diodes on $24 \mu\text{m}$ pitch) per layer or larger numbers of smaller arrays, and was comparable with the uniformity achieved by *Edwall* [15.76]. In the past, other workers have established MOVPE reactor designs capable of large-area uniform growth of CMT on 3 inch wafers [15.76, 77] but these activities have now ceased as attention has focused on MBE growth techniques.

The usual methods for determining depth uniformity of a CMT layer are sharpness of the infrared absorption edge and SIMS depth profiles (in particular looking at the Te^{125} secondary ion). The results from these techniques indicate that the IMP structure is fully diffused for IMP periods of the order of 1000 \AA and growth temperatures in the range of 350 to 400°C unless the surface becomes faceted during growth, when microinhomogeneities may occur [15.78].

15.3.1 Substrate Type and Orientation

The search for the correct substrate material and orientation has been a major area of research in CMT because it is a limiting factor in the quality of the epilayers. Essentially, there are two categories of substrates: (i) lattice-matched II–VI substrates and (ii) non-lattice-matched ‘foreign substrates’. Examples of the former are CdZnTe and CdSeTe, where the alloy compositions are tuned to the lattice parameter of the epilayer. Non-lattice-matched substrates include GaAs, Si and sapphire. The lattice mismatches can be up to 20% but, remarkably, heteroepitaxy is still obtained. The need for a ternary substrate to avoid substantial numbers of misfit dislocations has made the development of the CdTe-based substrate more complex. The small mismatch with CdTe substrates (0.2%) is sufficient to increase the dislocation density to greater than 10^6 cm^{-2} , comparable with some layers on CdTe-buffered GaAs, where the mismatch is 14% [15.76]. An additional problem encountered with the lattice-matched substrates is the lamella twins that form on (111) planes in Bridgman-grown crystals. It is possible to cut large ($4 \times 6 \text{ cm}$) (111)-oriented substrates parallel to the twins, but (100)

substrates have a much lower yield. MOVPE-grown CdTe also twins on the (111), and these twins will propagate through an entire structure. However, CMT growth on the (111)B face is very smooth for layers up to $20 \mu\text{m}$ thick, which is adequate for infrared detector structures.

The majority of MOVPE growth has concentrated on orientations close to (100), normally with a misorientation to reduce the size of macrodefects, known as hillocks or pyramids. Large Te precipitates can intersect the substrate surface and nucleate macrodefects. In a detailed analysis of the frequency and shapes of defects on different misorientations, it was concluded [15.79] that the optimum orientation was (100) $3-4^\circ$ towards the (111)B face. The presence of macrodefects is particularly critical for focal plane arrays, where they cause one or more defective pixels per defect. An alternative approach has been to use the (211)B orientation. In this case the surface appears to be free of macrodefects and is sufficiently misoriented from the (111) to avoid twinning. Dislocation densities of 10^5 cm^{-2} have been measured in CMT grown by IMP onto CdZnTe (211)B substrates [15.76], and diffusion-limited detectors have been fabricated using this orientation [15.80].

The alternative lattice-mismatched substrates were investigated as a more producible alternative to the variable quality of the CdTe family of substrates. As the CMT arrays must be cooled during operation, there is the risk that the differential thermal contraction between the substrate and multiplexer will break some of the indium contacting columns. The ideal substrate from this point of view is of course silicon, but the initial quality of heteroepitaxy with 20% lattice mismatch was poor. One of the most successful alternative substrate technologies has been the Rockwell PACE-I (producible alternative to CdTe epitaxy) which uses *c*-plane sapphire with a CdTe buffer layer grown by MOVPE and a CMT detector layer grown by LPE. The sapphire substrates absorb above $6 \mu\text{m}$ and can only be used for the $3-5 \mu\text{m}$ waveband. However, even with careful substrate preparation, a buffer layer thicker than $5 \mu\text{m}$ is needed to avoid contamination of the active layer.

GaAs has been the most extensively used alternative substrate, which has been successfully used to reduce the macrodefect density to below 10 cm^{-2} , and X-ray rocking curve widths below 100 arcs have been obtained [15.81]. Due to the large lattice mismatch, the layer nucleates with rafts of misfit dislocations that relieve any strain. The main cause of X-ray rocking curve broadening is the tilt associated with a mosaic structure that arises from the initial island growth.

Fig. 15.8 SIMS profile of a $p^+p^-\pi n^-n^+$ device structure grown on a 3 inch wafer. (After [15.74])

Both CdTe and GaAs have the zinc blende structure but because the lattice mismatch is so large there is a better match with the orientation relationship (111)|| (100). The growth orientation of a CdTe epilayer can be either (100) or (111) according to the nucleation conditions. Tellurium-rich conditions appear to favor the (111) nucleation but temperature and choice of precursors also play an important role. A method for ensuring that the (100) orientation is achieved (thus avoiding twin formation) is to grow a thin nucleation layer of ZnTe that has a lattice parameter between that of CdTe and GaAs.

The majority of the MOVPE growth onto silicon substrates has used a GaAs buffer layer to step the change in lattice parameter between silicon and CdTe. By growing a 12 μm -thick CdTe buffer layer, the X-ray rocking curve width is reduced to 120 arcs, larger than the best values obtained on GaAs substrates [15.82]. X-ray topography reveals the same type of mosaic structure as for CdTe on bulk GaAs substrates. The advantage of thermal expansion match with the silicon multiplexer has been demonstrated with a midwave 256×256 array where the entire structure was grown by MOVPE [15.83]. Hybrid arrays of 480×640 elements have also been made, where MOVPE-grown CdZnTe/GaAs/Si was used as a substrate for LPE growth of the active CMT structure [15.65].

15.3.2 Doping

The earliest FPAs were made in as-grown, undoped MOVPE layers where the p-type nature was due to

metal vacancies in the layers. However, for current and future FPAs, the more complex devices such as p/n heterostructures require extrinsic doping and low-temperature annealing in a mercury vapor to remove metal vacancies. Activation of donors is relatively easy using either Group III metals or Group VII halogens. Indium has been used for doping concentrations from $< 10^{15} \text{ cm}^{-3}$ up to 10^{18} cm^{-3} . The low concentrations are limited by residual donors and acceptors, with the Hall mobility being a very sensitive measure of compensation. For the p/n structures, the n-type side of the junction is the absorber layer and therefore minority carrier lifetime and diffusion length are also important. An alternative n-type doping approach is to use a halogen such as iodine or chlorine that substitutes on the Group VI sites. The first use of iodine doping [15.84] used a crystalline iodine source, where the vapor was transported via hydrogen flow and a separate injector. The main advantage of iodine over indium is the slower diffusion, which enables more abrupt doped structures to be grown. A liquid source, ethyl iodide (EtI), was used by Mitra et al. [15.85] to dope over a range from 10^{15} to 10^{18} cm^{-3} , with no apparent memory. Current work on doped heterostructures [15.74] uses isobutyl iodide (IBI), as levels over a more useful range of (mid- 10^{14} to mid- 10^{17} cm^{-3}) can be achieved with this source donor.

Acceptor doping, as in LPE processes, proved to be more problematic in MOVPE than donor doping. The first attempts at arsenic doping used AsH_3 that would normally be very stable at growth temperatures of 350°C . It was proposed by Capper et al. [15.86] that the AsH_3 forms an adduct with DMCD in the vapor and causes the deposition of As at a low temperature. It was found that the doping incorporation was much higher in the CdTe layers and that activation of the dopant could be changed by adjusting the VI/II ratio during growth. A second-generation acceptor dopant source (tris-dimethyl amino arsine (DMAAs)) is now the preferred way to introduce As into layers. Multilayer, fully doped heterostructures have been grown [15.74, 87] which demonstrate higher operating temperature performance due to Auger suppression techniques. These heterostructures were grown to investigate the device performance in the 3–5 μm and 8–12 μm IR bands. Figure 15.8 shows a SIMS profile of a 3–5 μm device structure grown on a 3-inch-diameter GaAs substrate. The excellent control over the As concentration allows the active region to be doped at $4\text{--}5 \times 10^{15} \text{ cm}^{-3}$ in the so-called ‘ π -layer’ of the heterostructure design. The iodine profile shows well-defined transitions that

help define the junction depth. Such layers have been fabricated into mesa test and 2-D arrays. These have been indium-bumped onto either test array carriers or Si multiplexers. This material represents the current state-of-the-art in MOVPE.

15.3.3 In Situ Monitoring

The use of optical in situ monitoring probes for MOVPE is helping to both elucidate the kinetic mechanisms and provide monitors suitable for feedback control. Although in situ monitoring is not widely used in CMT growth, there have been a number of notable examples

where progress has been made as a result of its application. The choice of monitoring technique depends on the film property that is of interest. For example, laser reflectometry will measure the bulk of the film, measuring film thickness, growth rate and some indication of film composition. Reflection difference spectroscopy (RDS) is sensitive to surface composition and will monitor surface reconstruction and adsorbate composition. Spectroscopic ellipsometry is very sensitive to film composition and is now becoming useful as an in situ monitor with fast multichannel analysis. A number of in situ characterization techniques have been outlined in a review [15.73].

15.4 Molecular Beam Epitaxy (MBE)

An alternative to MOVPE for the production of advanced multilayer heterostructures is growth by molecular beam epitaxy (MBE). Figure 15.9 shows a schematic of a simple molecular beam epitaxial system for the growth of semiconductors. Significant progress was made in CMT MBE technology in the 1990s [15.88–91]. Current CMT MBE technology offers low-temperature growth under an ultrahigh vacuum environment, in situ n-type and p-type doping, and control of composition, doping and interfacial profiles. All of these are essential for the growth of double-layer and multilayer structures for advanced FPAs and other novel devices. A typical system consists of eight interconnected chambers, including two growth chambers, two preparation chambers with integrated ion etching capabilities and entry chambers, an ESCALAB chamber, two buffer chambers and a transport chamber. Each growth chamber is equipped with dual Hg reservoirs, eight effusion cells and dual load locks for effusion cells to enable recharging of the materials without breaking the vacuum. The system is modular in nature and designed to accommodate sample sizes up to 3 inch in diameter.

Normally, growth of CMT is carried out at 180–190 °C on (211) CdZnTe substrates using Hg, CdTe and Te sources. Typically, the CdZnTe substrates are first degreased, then etched in Br-methanol solution, and then rinsed with methanol. The substrates are blown with dry nitrogen and mounted on holders, and then thermally cleaned at 350–400 °C under vacuum to remove oxides prior to growth [15.92]. Although MBE is essentially a nonequilibrium growth process, the vapor pressure of the constituent species over a CMT layer is governed

by thermodynamics. It has been shown [15.93] that the vapor pressure of Hg over a CMT layer at 170 °C is $\approx 7 \times 10^{-4}$ mbar and 8 mbar for the Te-rich and Hg-rich sides of the phase boundary, respectively. The value of the Hg vapor pressure on the Te-rich side of the phase boundary is similar to the beam equivalent pressure of

Fig. 15.9 Schematic of a simple molecular beam epitaxial system for the growth of semiconductors

Fig. 15.10 CMT MBE growth facility. (After O.K. Wu et al., in [15.4] p. 97)

Hg employed for the growth of CMT by MBE, suggesting that CMT growth occurs on the Te-rich side of the phase boundary, and RHEED studies confirm this. Although Hg is the more mobile species, which is likely to attach at step edges, sufficient mobility of the Cd species is critical for the growth of high-quality films.

The CMT alloy composition can be readily varied by choosing the appropriate beam-flux ratio. Over the range from $x = 0.2 - 0.50$, excellent control of composition can be achieved readily by varying the CdTe source flux with a constant flux of Hg at 3×10^{-4} mbar and Te at 8×10^{-7} mbar during the MBE growth [15.91].

The most widely used n-type dopant for CMT alloys during MBE growth is indium [15.94, 95]. The In concentration can be varied from 2×10^{15} to $5 \times 10^{18} \text{ cm}^{-3}$ by adjusting the In cell temperature ($450 - 700^\circ\text{C}$) with no evidence of a memory effect. The doping efficiency of In was almost 100%, evident from the Hall measurement and secondary ion mass spectrometry (SIMS) data, for carrier concentrations $< 2 \times 10^{18} \text{ cm}^{-3}$. As in several bulk growth techniques, and in LPE and MOVPE processes, donor doping is seen to be much easier than acceptor doping in MBE growth.

A critical issue when growing advanced CMT structures is the ability to grow high-quality p-type materials in situ. As, Sb, N, Ag and Li have all been used as acceptors during MBE growth of CMT, with varying degrees of success [15.96]. Most data available is centered on the use of arsenic, and two approaches have been investigated. The first approach is based on photoassisted MBE to enable high levels of p-type As-doping of CdTe [15.95]. For As-doping during composition-

ally modulated structure growth, only the CdTe layers in a CdTe-CMT combination are doped, as in MOVPE growth. Since the CdTe does not contain Hg vacancies, and is grown under cation-rich conditions, the As is properly incorporated onto the Te site and its concentration is proportional to the As flux. The structure then interdiffuses after annealing at high temperature to remove residual Hg vacancies, resulting in p-type, homogeneous CMT. The main disadvantage of this approach is that it requires a high-temperature anneal that results in reduced junction and interface control. An alternative approach is to use cadmium arsenide and correct Hg/Te ratios to minimize Hg vacancies during CMT growth [15.94]. As a result, the As is directed to the Group VI sublattice to promote efficient p-type doping. The main growth parameters that determine the properties of As-doped p-type CMT are the growth temperature and Hg/Te flux ratio. A comparison of the net hole concentration and the SIMS measurement indicates that the electrical activity of the As acceptors exceeds 60%.

Lateral compositional and thickness uniformity, evaluated by nine-point FTIR measurements, were performed on a $2.5 \times 2.5 \text{ cm}^2$ sample, and the results showed that the average alloy composition and thickness were $x = 0.219 \pm 0.0006$ and $t = 8.68 \pm 0.064 \mu\text{m}$, respectively [15.91].

The surface morphology of CMT layers is important from a device fabrication point of view. Scanning electron microscopy (SEM) studies indicate that surface morphology of MBE-grown CMT alloys is very smooth for device fabrication, except for occasional small undulations ($< 1 \mu\text{m}$). The excellent crystal quality of CMT layers grown by MBE is illustrated by X-ray rocking curve data for a LWIR double-layer heterojunction structure. The In-doped n-type (about $8 \mu\text{m}$ thick) base layer peak has a width of < 25 arcs and is indistinguishable from the CdZnTe substrate. Because the As-doped p-type cap layer is much thinner (about $2 \mu\text{m}$) and has a different alloy composition, its peak is broader (45 arcs), but the X-ray FWHM width still indicates high quality [15.91].

Other material properties such as minority carrier lifetime and etch pit density of the material are important for device performance. The lifetime of the photoexcited carriers is among the most important, since it governs the diode leakage current and the quantum efficiency of a detector. In the case of In-doped n-type layers ($x = 0.2 - 0.3$), results show that the lifetime ranges from $0.5 - 3 \mu\text{s}$ depending upon the x value and carrier concentration. Measured

lifetimes at 77 K approach the Auger recombination limit [15.97].

Extended defects including dislocations, pinholes, particulates, inclusions, microtwins, precipitates and inhomogeneities occur over lengths of several micrometers and are often observable by selective etching and microscopy [15.59]. Optical microscopy studies of etched MBE-grown CMT base layers indicate that the EPD of device-quality alloys is on the order of $2 \times 10^5 \text{ cm}^{-2}$, which is in good agreement with the lifetime data and comparable to the best LPE materials for device applications.

15.4.1 Double-Layer Heterojunction Structures

Two approaches have been used to achieve these structures, namely ion implantation and in situ doping, in CMT MBE [15.96]. The advantage of the in situ doping approach is that it is a simple layer-by-layer growth process and so it is relatively easy to grow multilayer structures. Reproducible p-type doping with low defect density is difficult to achieve, and it requires very stringent passivation for mesa structures. However, high-performance CMT 64×64 and 128×128 FPAs for MWIR and LWIR infrared detection using CMT double-layer heterojunction structures (DLHJ) grown by MBE have been demonstrated [15.98]. The performances of detectors fabricated from MWIR and LWIR layers compare very well to those from the LPE-based production process.

15.4.2 Multilayer Heterojunction Structures

In recent years, as infrared technology has continued to advance, the demand for multispectral detectors has grown. The original growth process developed for the DLHJ structures was applied and extended for the growth of n-p-p-n multilayer heterojunction (MLHJ) structures for two-color detector applications [15.99]. A SIMS profile of an MLHJ structure confirms that the in situ doping process is able to incorporate $> 2 \times 10^{18} \text{ cm}^{-3}$ As and control the n-type doping at $1\text{--}2 \times 10^{15} \text{ cm}^{-3}$ for both absorbing layers [15.100]. X-ray rocking curve measurement indicates that the FWHM is about 50 arcs for this structure, suggesting high-quality material. This dual-band detector is basically a four-layer structure with two p-n junctions, one for each spectral band. The top and bottom layers are the IR absorbers while the middle two layers are transparent. The spectral re-

Fig. 15.11 The spectral response data for the MW-LWIR two-color detectors fabricated from a *n-p-p-n* multilayer heterojunction structure. The data indicate that the MWIR is detected in negative bias mode and LWIR is detected under forward bias conditions, as expected. (After O.K. Wu et al., in [15.4] p. 97)

sponse of this MW/LW two-color detector is shown in Fig. 15.11. This preliminary demonstration indicated that CMT MBE in situ doping technology is capable of growing multilayer structures for advanced IRFPAs.

15.4.3 CMT and CdZnTe Growth on Silicon

The move to using Si substrates for the epitaxial growth of CMT infrared IRFPAs is motivated by several important technological factors [15.91]. Primarily there is the need to establish a thermal expansion match between the Si readout electronics chip and the array of CMT infrared detectors. As the size of such CMT hybrid IRFPAs increases, long-term thermal cycle reliability can be compromised by the thermal expansion mismatch between Si and bulk CdZnTe substrates. One approach to solving this problem requires the fabrication of the CMT array on a Si substrate, rather than bulk CdZnTe, so that the array's thermal expansion is constrained to match that of the Si readout chip. Considerable research activity [15.101–104] has been directed towards achieving epitaxial deposition of high crystalline quality CMT films on Si substrates. Beyond their thermal expansion match to the readout electronics ship, Si substrates for IRFPAs offer additional advantages when compared with CdZnTe substrates; for example, they are more readily available in larger sizes with superior mechan-

ical strength and at substantially lower cost. The use of Si substrates also avoids potential problems associated with outdiffusion of fast-diffusing impurities, such as Cu, that has been identified [15.105] as a recurring problem with CdZnTe substrates. Finally, development of the technology for epitaxial growth of CMT on Si will ultimately be a requisite technology should monolithic integration of IR detector and readout electronics on a single Si chip become a goal of future IRFPA development.

However, the most serious technical challenge faced when fabricating device-quality epitaxial layers of CMT on Si is the reduction in the density of threading dislocations that results from the accommodation of the 19% lattice constant mismatch and the large difference in thermal expansion coefficients between Si and CMT. Dislocation density is known to have a direct effect on IR detector performance [15.58], particularly at low temperature. All efforts to fabricate CMT IR detectors on Si substrates have relied upon the prior growth of CdZnTe buffer layers on Si. Growth of $\approx 5\text{ }\mu\text{m}$ of CdZnTe is required to allow dislocation annihilation processes to decrease the dislocation density to low 10^6 cm^{-2} [15.104].

As an additional step, initiation layers of ZnTe have been used to facilitate parallel MBE deposition of CdTe(001) on Si(001) [15.98, 102]; ZnTe nucleation layers are also commonly used for the same purpose for the growth of CdZnTe on GaAs/Si substrates by other vapor-phase techniques [15.106]. CdTe(001) films with rocking curves as narrow as 78 arcsec and

EPD of $1\text{--}2\times 10^6\text{ cm}^{-2}$ have been demonstrated with this technique. Both (111)- and (001)-oriented MBE CdTe/Si substrates have been used as the basis for demonstrating LPE-grown CMT detectors [15.98, 101]. The (001)-oriented CdTe/Si films have been used in demonstrations of 256×256 CMT hybrid arrays on Si [15.98].

Current state-of-the-art MBE material on four-inch-diameter Si substrates has been discussed by Varesi et al. [15.107, 108]. Dry etching is used to produce array sizes of 128×128 and 1024×1024 with performances equivalent to LPE material. Similar material, grown on CdZnTe this time, by another group [15.109] in the MW and SW regions is used in astronomical applications (see [15.110]).

Other recent applications of MBE-grown CMT include very long wavelength arrays (onto (211)B CdZnTe substrates) by Philips et al. [15.111], two-color (MW $4.5\text{ }\mu\text{m}$ /SW $2.5\text{ }\mu\text{m}$) arrays of 128×128 diodes [15.69, 112], gas detectors in the $2\text{--}6\text{ }\mu\text{m}$ region [15.113] and $1.55\text{ }\mu\text{m}$ avalanche photodiodes using Si substrates [15.66]. All of these applications demonstrate the versatility of the CMT MBE growth technique.

One final point to note about the current devices being researched in MOVPE and MBE (and to a lesser extent LPE) processes is that growth is no longer of single layers from which the detector is made; instead the materials growers are actually producing the device structures within the grown layer. This is particularly true of the fully doped heterostructures grown by MOVPE and MBE shown in Figs. 15.8 and 15.11.

15.5 Alternatives to CMT

Rogalski [15.1, 114] has provided details about several Hg-based alternatives to CMT for infrared detection. He concludes that only HgZnTe and HgMnTe are serious candidates from the range of possibilities. Theoretical considerations of Sher et al. [15.115] showed that the Hg–Te bond is stabilized by the addition of ZnTe, unlike the destabilization that occurs when CdTe is added, as in CMT.

The pseudobinary phase diagram of HgZnTe shows even more separation of solidus and liquidus than the equivalent for CMT, see Fig. 15.12. This leads to large segregation effects, large composition variations for small temperature changes, and the high Hg vapor pressure presents the usual problems of containment. HgTe and MnTe are not completely miscible over the entire

range; the single-phase region is limited to $\lesssim x \lesssim 0.35$. The solidus–liquidus separation in the HgTe–MnTe pseudobinary is approximately half that in CMT, so for equivalent wavelength uniformity requirements any crystals of the former must be much more uniform than CMT crystals.

Three methods: Bridgman, SSR and THM are the most popular ones for the bulk growth of HgZnTe and HgMnTe. The best quality crystals have been produced by THM [15.116], with uniformities of ± 0.01 in both the axial and radial directions for HgZnTe. For HgMnTe, Bodnaruk et al. [15.117] produced crystals of $0.04 < x < 0.2$ with uniformities of ± 0.01 and ± 0.005 in the axial and radial directions, while Gille et al. [15.118] grew $x = 0.10$ crystals with ± 0.003 along

Fig. 15.12 HgTe-ZnTe and HgTe-CdTe pseudobinary phase diagrams. (After [15.120])

a 16 mm-diameter slice. *Becla et al.* [15.119] achieved decreased radial variations by applying a magnetic field.

These bulk crystals are suitable for some device architectures, but higher performance is obtained in more sophisticated structures that can only be made by epitaxial techniques. The advantages are the usual ones of lower growth temperature, lower Hg vapor pressure, shorter growth times and less precipitation with improved uniformity of composition. These features have been discussed in detail and descriptions of the various epitaxial processes given by *Rogalski* [15.114, 120, 121]. *LPE* growth of HgCdZnTe and HgCdMnTe by *Uchino* and *Takita* [15.122] showed that incorporation of Zn or Mn improved the uniformity of composition. HgMnTe films have been grown by *MOCVD* using the *IMP* technique, with both n- and p-type layers being produced. As

Fig. 15.13 Energy gap versus lattice parameter in Hg-based ternary alloy systems at room temperature. The bold lines indicate ranges of x for which homogeneous crystal phases form. (After A. Rogalski, in [15.6] p. 377)

in all epitaxial growth techniques, there is a need for suitable (nearly lattice-matched) large-area single-crystal substrates. Figure 15.13 shows the lattice constants of the Hg-based alloy systems at room temperature. There are larger differences between the lattice parameters of HgTe and ZnTe and HgTe and MnTe than between HgTe and CdTe. At first sight it would appear that CdMnTe would be a suitable substrate system for these ternary alloys, but CdMnTe crystals grown by the Bridgman process are highly twinned and therefore unsuitable for use as substrates.

The device aspects of these alternative ternary systems are discussed in the chapter by Baker in this Handbook.

16. Wide-Bandgap II–VI Semiconductors: Growth and Properties

Wide-bandgap II–VI compounds have been applied to optoelectronic devices, especially light-emitting devices in the short-wavelength region of visible light, because of their direct gap and suitable bandgap energies. Many methods have been extensively applied to grow high-quality films and bulk single crystals from the vapor and liquid phases.

This chapter firstly discusses the basic properties and phase diagrams of wide-bandgap II–VI compounds such as ZnS, ZnO, ZnSe, ZnTe, CdSe and CdTe. Then the growth methods and recent progress in films and bulk crystal growth are reviewed. In the epitaxial growth methods, the focus is on liquid-phase epitaxy (LPE), vapor-phase epitaxy (VPE) containing conventional VPE, hot-wall epitaxy (HWE), metalorganic chemical vapor deposition (MOCVD) or metalorganic phase epitaxy (MOVPE), molecular-beam epitaxy (MBE) and atomic-layer epitaxy (ALE). In bulk crystal growth, two typical growth methods,

16.1	Crystal Properties	326
16.1.1	Basic Properties	326

16.3.5	Other Methods	338
16.4	Conclusions	339
	References	340

chemical/physical vapor transport (CVT/PVT) and Bridgman techniques, are introduced.

Wide-bandgap II–VI compounds are expected to be one of the most vital materials for high-performance optoelectronics devices such as light-emitting diodes (LEDs) and laser diodes (LDs) operating in the blue or ultraviolet spectral range. Additionally, the high ionicity of these compounds makes them good candidates for high electro-optical and electromechanical coupling. The basic promises of wide-bandgap materials can be found in Fig. 16.1.

Thin films were commonly grown using the conventional vapor-phase epitaxy (VPE) method for 60 s. With the development of science and technology, new and higher requirements arose for material preparation. For this reason, novel epitaxial growth techniques were developed, including hot-wall epitaxy (HWE) [16.1], metalorganic chemical vapor deposition (MOCVD) [16.2], molecular-beam epitaxy (MBE) [16.3], metalorganic molecular-beam epitaxy (MOMBE) [16.4] and atomic-layer epitaxy (ALE) [16.5]. Using these growth methods, film thickness can be controlled, and quality can be improved.

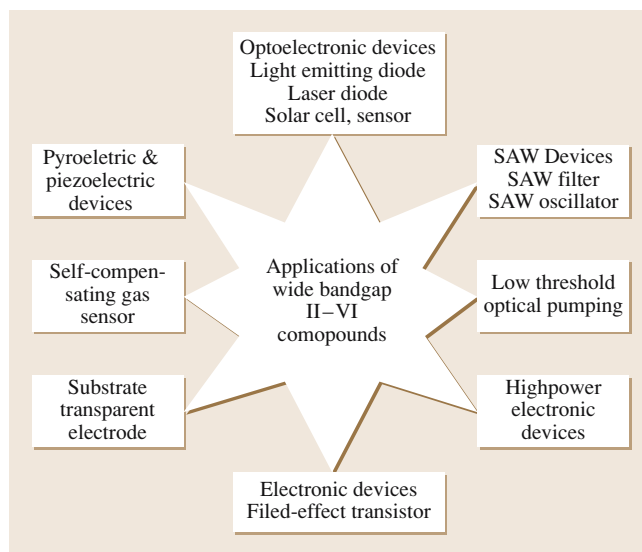

Fig. 16.1 Application of II–VI wide-bandgap compounds

On the other hand, basic research work into growing bulk crystals of wide-bandgap II–VI compounds has been carried out. Focus was put on high-purity, high-quality, large single crystals [16.6–10]. Since the electrical and optical properties of semiconductor compounds are drastically affected by impurities and native defects, purity and quality are very important for fundamental research and engineering application where they are used as substrates. Bulk single crystals of these wide-bandgap II–VI compounds have been grown from the vapor, liquid and solid phases. Vapor-phase growth includes chemical vapor transport (CVT) and physical vapor transport (PVT) methods; liquid-phase methods includes growth from the melt or solvent. Among these growth methods, melt growth is most suitable to produce sizable bulk crystals for relatively short growth duration. Growth methods for films and bulk crystals of wide-bandgap II–VI compounds are summarized in Fig. 16.2 and the details can be found in Sects. 16.2 and 16.3.

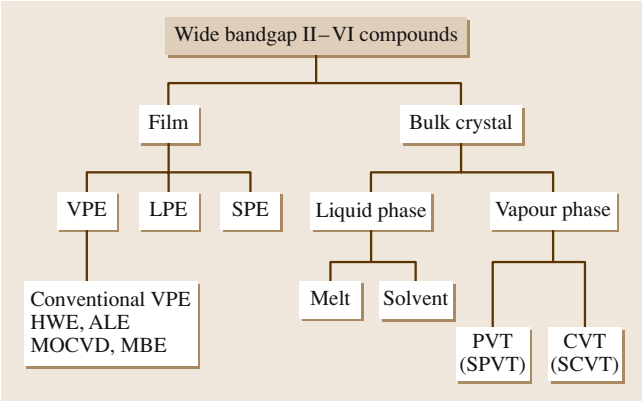

Fig. 16.2 Film and bulk-crystal growth techniques for II–VI wide-bandgap compounds

16.1 Crystal Properties

16.1.1 Basic Properties

Wide-bandgap compound semiconductors have higher melting points. Due to their high ionicity, the overheating phenomenon occurs when they are heated to their melting point. Owing to the higher vapor pressures at their melting points, it is difficult to grow bulk crystals from melt. On the other hand, it is easy to grow bulk crystals as well as their films from the vapor phase. Therefore,

This chapter firstly describes the physical and chemical properties of these wide-bandgap II–VI compounds, then reviews the growth techniques and introduces the main results in preparing film and bulk single crystals of ZnS, ZnO, ZnSe, ZnTe, CdTe, and so on.

Fig. 16.3a–g Phase diagrams of some main wide-bandgap II–VI compounds. (a) ZnS, (b) ZnSe, (c) ZnSe phase diagram near the congruent point; (d) ZnTe; (e) CdSe; (f) CdTe; (g) CdTe phase diagram near the congruent point

before introducing film and bulk crystal growth, it is necessary to review their physical and chemical properties. Table 16.1 shows the properties of some of the main II–VI compound semiconductor materials [16.11–24].

16.1.2 Phase Diagram

It is necessary to understand the phase diagram to grow high-quality film and bulk single crystals. Figure 16.3

Table 16.1 Properties of some wide-bandgap II–VI compound semiconductors

Material Property	ZnS	ZnO	ZnSe	ZnTe	CdS	CdSe	CdTe
Melting point (K)	2038 (WZ, 150 atm)	2248	1797	1513	2023 (WZ, 100 atm)	1623	1370 (ZB)

shows the phase diagrams reported for ZnS [16.25], ZnSe [16.25, 26], ZnTe [16.25], CdSe [16.27] and CdTe [16.28, 29]. Although much work has been done, there some exact thermodynamic data are still

lacking, especially details close to the congruent point. Unfortunately, the phase diagram of ZnO is not available in spite of its growing importance in applications.

16.2 Epitaxial Growth

Epitaxial growth of wide-bandgap II–VI compounds was mainly carried out using liquid-phase epitaxy (LPE), or VPE. VPE includes several techniques, such as conventional VPE, hot-wall epitaxy (HWE), met-

alorganic chemical vapor deposition (MOCVD) or metalorganic phase epitaxy (MOVPE), molecular-beam epitaxy (MBE), metalorganic molecular-beam epitaxy (MOMBE) and atomic-layer epitaxy (ALE), etc. Each

Table 16.2 Strengths and weaknesses of several epitaxial growth techniques

LPE	Thermodynamic equilibrium growth Easy-to-use materials Low-temperature growth High purity Multiple layers Thickness control not very precise Poor surface/interface morphology	MOCVD	Gaseous reaction for deposition Precise composition Patterned/localized growth Potentially easier large-area multiple-wafer scale-up Low-temperature growth High-vapor-pressure materials growth allowed About 1 ML/s deposition rate Expensive equipment Safety precautions needed
HWE	Easy-to-use materials Low cost Thermodynamic equilibrium Hard to grow thick layers Thickness control not very precise	MBE and MOMBE	Physical vapor deposition Ultra-high-vacuum environment About 1 ML/s deposition rate In situ growth-front monitoring Precise composition Low growth rate Sophisticated equipment Limit for high-vapor-pressure materials growth (MBE)
VPE	Easy to operate Economic Thinner layers High growth rates Easier composition control High temperature (800–1000 °C)		
ALE	Gaseous reaction for deposition Low-temperature growth Precise composition Low growth rate Safety precautions needed		

of these methods has its advantages and disadvantages. They are summarized in Table 16.2.

In the case of hetero-epitaxy, the mismatch between substrate material and epitaxial layer affects the growing structure and quality of the epitaxial layer. The mismatch should be made as small as possible when choosing the pair of materials (substrate and epitaxial material). Furthermore, the difference between the thermal expansion coefficients of the pair of materials has to be considered to obtain high-quality epitaxial layer [16.30].

16.2.1 The LPE Technique

LPE growth occurs at near-thermodynamic-equilibrium conditions. There are two growth methods. The first is called equilibrium cooling, in which the saturated solution is in contact with the substrate and the temperature is lowered slowly, the solution becomes supersaturated; meanwhile a slow epitaxial growth on the substrate is ini-

tiated. The second is the step-cooling process, in which the saturated solution is cooled down a few degrees (5–20 K) to obtain a supersaturated solution. The substrate is inserted into the solution, which is kept at this cooled temperature. Growth occurs first due to the supersaturation, and will slow down and stop finally. For both techniques, if the substrate is dipped in sequence into several different melt sources, multiple layer structures can be grown. **LPE** can successfully and inexpensively grow homo- and heterostructures. As the growth is carried out under thermal equilibrium, an epilayer with a very low native defect density can be obtained.

The **LPE** method can be used to grow high-quality epilayers, such as ZnS [16.31], ZnSe [16.31, 32], ZnSSe [16.33], ZnTe [16.34], etc. *Werkhoven et al.* [16.32] grew ZnSe epilayers by **LPE** on ZnSe substrates in a low-contamination-level environment. In their study, the width of bound exciton lines in low-temperature photoluminescence spectra was used

Fig. 16.4 A typical VPE growth system

to define the quality of the material, and the energy of the lines was used to identify trace impurities. The photoluminescence (PL) results showed that the ZnSe epitaxial layer has the high quality. The sharpest spectra occurred in layers grown rapidly on a previously grown buffer layer, indicating the importance of impurity out-diffusion from the substrate into the growing layer. The sharpness of these bound exciton lines indicates that the total concentration of electrically active impurities ($N_A + N_D$) was below 10^{17} cm^{-3} .

16.2.2 Vapor-Phase Epitaxy Techniques

Conventional VPE

A typical VPE growth system is shown in Fig. 16.4. In VPE growth, thin films are formed by the deposition of atoms from the vapor phase. There are two types of transport mechanisms for the source materials, physical vapor deposition (PVD) without any chemical reaction, and chemical vapor deposition (CVD), where the formation of the deposited film is the result of a chemical reaction

of the precursors on the substrate. In VPE growth, there are several important parameters, such as the source temperature, the substrate temperature, the flow rate of the carrier gas, the growth pressure, and so on. These determine the growth rate, composition, and crystallinity of the epitaxial layers.

The VPE technique is the most popular in semiconductor epitaxial growth. Since the vapor pressures of all wide-bandgap II–VI materials are high, their epitaxial layers can be grown by this method. As an example, high-quality ZnS single-crystal films have been grown on a Si substrate using hydrogen as a carrier gas [16.35, 36]. Furthermore, the Iida group [16.37] doped N and P into a ZnS epilayer and studied their behavior in details. The N and P were expected to compensate the native donor state and to result in an insulating material. The results showed that the doped acceptors N and P reduced the donor density and an insulating material was obtained. Later, this group was successful in preparing a p-type ZnS epilayer using NH_3 as an acceptor dopant [16.38]. Many efforts have been made to grow ZnSe epilayers on different substrates, especially on GaAs in the past two decades [16.39, 40]. p-type ZnSe was also obtained by this technique [16.41]. In addition, other compounds, ZnTe [16.42], CdS [16.43], CdSe [16.44], and CdTe [16.45], were also studied using this technique.

The HWE Technique

Hot-wall epitaxy [16.1] has proved to be a very successful growth method for II–VI compound epitaxial layers. Its principal characteristic is the growth of thin films under conditions near thermodynamic equilibrium. Compared with other VPE methods, the HWE technique has the advantages of low cost, simplicity, convenience, and relatively high growth rate. In particular, it can control deviation from stoichiometry during growth of an epilayer.

A schematic diagram of the improved HWE system is showed in Fig. 16.5; it consists of four independent furnaces. The source material placed at the middle is transported to the substrate. The region of the growth reactor between the source and substrate, called the hot wall, guarantees a nearly uniform and isotropic flux of molecules onto the substrate surface. To control the deviation from stoichiometry, the reservoir part is placed at the bottom with a constituent element.

HWE has been applied to growing II–VI compound epilayers, such as CdTe [16.46], CdS [16.47], CdSe [16.48], ZnTe [16.49], and also to producing heterostructures for laser and photovoltaic detector fab-

Fig. 16.5 Diagram of a typical HWE system growth chamber

rication [16.50]. Most research using HWE technique has focused on CdTe growth. Wang et al. [16.46] optimized growth conditions and grew high-quality CdTe epitaxial films using the HWE apparatus shown in Fig. 16.5. All the CdTe epilayers show mirror-like surfaces. Results from PL and X-ray diffraction (XRD) show that CdTe epilayers on GaAs suffer from a biaxial compressive stress, that this stress is rapidly relaxed within a thickness of about 5 μm , and that it remains in the epilayer up to a film thickness of 15 μm . Although this heterosystem has a 14.6% lattice mismatch and -26% thermal expansion mismatch at 300 K, high-quality CdTe epilayers, with a full-width half-maximum (FWHM) of 0.26 meV for bound-exciton emission lines in 4.2-K PL, about 90 arcs for (400) diffraction in four-crystal XRD spectrum, were prepared by selecting suitable growth conditions and epilayer thickness.

Recently, significant results have been achieved for CdTe/Si (111) epilayer growth by HWE. Lalev et al. [16.51] reported that high-quality CdTe (111) epilayers with A polarity were directly grown on hydrogen-terminated Si (111) without any preheating treatment. Through the originally designed two-step growth regime, the crystal quality of CdTe film was significantly improved, and the best FWHM value of 118 arcs from four-crystal rocking curves was obtained for a 5- μm -thick epilayer.

The MOCVD Technique

MOCVD or MOVPE is an improvement over conventional VPE. Since its introduction in 1968 [16.52], this technique has been established as one of the techniques for epitaxial growth of compound semiconductors both for research and production. The factors that have allowed MOCVD to reach this popularity are the purity and abruptness of the grown layers together with the flexibility of the technique, which makes the growth of almost all compound semiconductors possible. This abrupt transition in the composition of the epitaxial structure is necessary for the fabrication of digital or analog alloy system.

The development history of MOCVD technique is equivalent to that of source precursors. Since ZnSe epilayers were grown by MOCVD [16.52], many source precursors of II–VI elements have been developed. $\text{Zn}(\text{CH}_3)_2$ dimethylzinc (DMZn) and $\text{Zn}(\text{C}_2\text{H}_5)_2$ diethylzinc (DEZ) were used at the beginning of MOCVD growth [16.53]. ZnSe and ZnS films were grown using these metalorganic sources and inorganic H_2Se or H_2S . Unfortunately, the quality of these films was very poor. For this reason, $\text{Se}(\text{CH}_3)_2$ dimethylselenide (DMS_{Se}) and $\text{Se}(\text{C}_2\text{H}_5)_2$ diethylselenium (DESe) were developed [16.54]. The quality of epilayers was greatly improved. From then, II and VI elemental gas precursors were proposed one after another. Wright et al. grew a ZnSe film using $(\text{DMZn}(\text{NET}_3)_2)$ triethylamine adduct of dimethylzinc [16.55]. Hirata et al. [16.56] and Nishimura et al. [16.57] proposed methylselenol (MSeH) and tertiarybutylselenol (*t*-BuSeH) as Se sources, respectively. Methylallylselenide (MASE) [16.58], diallyl-selenide (DASE) [16.59], *t*-butylallylselenide (*t*-BuASE) [16.60], tertiarybutyl-selenide (*Dr*-BuSe) [16.61], were also used as Se sources. Fujita et al. found methylmercaptan (MSH) as an S source [16.53]. Besides these, many other source precursors of II–VI elements, such as $\text{Cd}(\text{CH}_3)_2$ dimethylcadmium (DMCd) [16.62], $\text{Te}(\text{CH}_3)_2$ dimethyltelluride (DMTe) [16.62], $\text{Te}(\text{C}_2\text{H}_5)_2$ diethyltelluride (DETe), $\text{Te}(\text{C}_3\text{H}_7)_2$ diisopropyltelluride (DIPTe) [16.63], $\text{S}(\text{C}_2\text{H}_5)_2$ diethylsulfide (DES), $\text{S}(\text{C}_4\text{H}_9)_2$ ditertiarybutylsulfide (DTBS), $(\text{C}_4\text{H}_9)\text{SH}$ tertiarybutylthiol (*t*BuSH), have been used.

The great advantage of using metalorganics is that they are volatile at moderately low temperatures. Since all constituents are in the vapor phase, precise electronic control of gas flow rates and partial pressures is possible. This, combined with pyrolysis reactions that are

relatively insensitive to temperature, allows efficient and reproducible deposition.

The substrate wafer is placed on a graphite susceptor inside a reaction vessel and heated by a radio-frequency (RF) induction heater. The growth temperature depends on the type of compounds grown. Growth is carried out in a hydrogen atmosphere at a pressure of 100–700 torr. The growth precursors decompose on contact with the hot substrate to form epitaxial layers. Each layer is formed by switching the source gases to yield the desired structure.

The films of almost all wide-bandgap II–VI compounds have been grown by MOCVD technique. Most work has been done on p-ZnSe epilayers in the past two decades [16.64–66]. The highest hole concentration of $8.8 \times 10^{17} \text{ cm}^{-3}$ was reported with a NH_3 doping source [16.67]. Recently, quantum wells (QW) and quantum dots (QD) of these wide-bandgap compounds have become the focus. Successful pulsed laser operation at 77 K in ZnCdSe/ZnSe/ZnMgSSe QW-structure separated-confinement heterostructures has been realized [16.68].

MBE and MOMBE

MBE was developed at the beginning of the 1970s to grow high-purity high-quality compound semiconductor epitaxial layers on some substrates [16.69, 70]. To date, it has become a very important technique for growing almost all semiconductor epilayers. An MBE system is basically a vacuum evaporation apparatus. The pressure in the chamber is commonly kept below $\approx 10^{-11}$ torr. Any MBE process is dependent on the relation between the equilibrium vapor pressure of the constituent elements and that of the compound [16.71]. There are a number of features of MBE that are generally considered advantageous for growing semiconducting films: the growth temperature is relatively low, which minimizes any undesirable thermally activated processes such as diffusion; the epilayer thickness can be controlled precisely; and the introduction of different vapor species to modify the alloy composition and to control the dopant concentration can be conveniently achieved by adding different beam cells with proper shutters. These features become particularly important in making structures involving junctions.

Metalorganic molecular-beam epitaxy growth (MOMBE) is one of the variations of the MBE system [16.72, 73]. The difference is that metalorganic gaseous sources are used as the source materials. Therefore, this growth technique has the merits of MOCVD and MBE.

MBE or MOMBE techniques have been used to grow epilayers of almost all wide-bandgap II–VI semiconductors [16.74, 75]. Due to its features, it is very successful in growing super-thin layers, such as single quantum wells (SQW), multiple quantum wells (MQW) [16.76, 77] and nanostructures [16.78].

In nanostructures, quantum dot (QD) structures have attracted a lot of attention in recent years. This field represents one of the most rapidly developing areas of current semiconductor. They present the utmost challenge to semiconductor technology, rendering possible fascinating novel devices. QD are nanometer-size semiconductor structures where charge carriers are confined in all three spatial dimensions. They are neither atomic nor bulk semiconductor, but may best be described as artificial atoms.

In the case of heteroepitaxial growth there are three different growth modes [16.79]: (a) Frank–van der Merwe (FM) or layer-by-layer growth, (b) Volmer–Weber (VW) or island growth, and (c) Stranski–Krastanov (SK) or layer-plus-island growth. Which growth mode will be adopted in a given system depends on the surface free energy of the substrate, (σ_s), that of the film, (σ_f), and the interfacial energy (σ_i). Layer-by-layer growth mode occurs when $\Delta\sigma = \sigma_f + \sigma_i - \sigma_s = 0$. The condition for FM-mode growth is rigorously fulfilled only for homoepitaxy, where $\sigma_s = \sigma_f$ and $\sigma_i = 0$. If the FM-mode growth condition is not fulfilled, then three-dimensional crystals form immediately on the substrate (VW mode). For a system with $\Delta\sigma = 0$ but with a large lattice mismatch between the substrate and the film, initial growth is layer-by-layer. However, the film is strained. As the film grows, the stored strain energy increases. This strained epilayer system can lower its total energy by forming isolated thick islands in which the strain is relaxed by interfacial misfit dislocations, which leads to SK growth in these strained systems. The SK growth mode occurs when there is a lattice mismatch between the substrate and the epilayer, causing the epilayer to be strained, which results in the growth of dot-like self-assembled islands. Wire-like islands can grow from dot-like islands via a shape transition which helps strain relaxation.

For nanostructure fabrication, a thin epilayer is usually grown on a substrate. This two-dimensional (2-D) layer is used to fabricate lower-dimensional structures such as wires (1-D) or dots (0-D) by lithographic techniques. However, structures smaller than the limits of conventional lithography techniques can only be obtained by self-assembled growth utilizing the principles of SK or VW growth. For appropriate growth condi-

tions, self-assembled epitaxial islands can be grown in reasonably well-controlled sizes [16.80].

Because wide-bandgap II–VI materials typically have stronger exciton–phonon interactions than III–V materials, their nanostructures are expected to be very useful in fabricating optoelectronics devices and in exploring the exciton nature in low-dimensional structure. Self-assembled semiconductor nanostructures of different system, such as CdSe/ZnSe [16.81], ZnSe/ZnS [16.82], CdTe/ZnTe [16.83], CdS/ZnSe [16.84], are thought to be advantageous for future application. MBE/MOMBE [16.81, 84], MOCVD [16.82], HWE [16.85] are the main growth techniques used to obtain such structures. MBE is the most advanced technique for the growth of controlled epitaxial layers. With the advancement of nanoscience and nanotechnology, lower-dimensional nanostructures are being fabricated by lithographic techniques from two-dimensional epitaxial layers. Alternately, self-assembled, lower-dimensional nanostructures can be fabricated directly by self-assembly during MBE growth.

Atomic–Layer Epitaxy

ALE is a chemical vapor deposition technique [16.5] where the precise control of the system parameters (pres-

sure and temperature) causes the reaction of adsorption of the precursors to be self-limiting and to stop with the completion of a single atomic layer. The precursors are usually metalorganic molecules. The special feature of ALE is that the layer thickness per cycle is independent of subtle variations of the growth parameters. The growth rate is only dependent on the number of growth cycles and the lattice constant of the deposited material. The conditions for thickness uniformity are fulfilled when material flux on each surface unit is sufficient for monolayer saturation. In an ALE reactor, this means freedom in designing the precursor transport and its interaction with the substrates.

The advantages obtainable with ALE depend on the material to be processed and the type of application. In single-crystal epitaxy, ALE may be a way to obtain a lower epitaxial crystal-growth temperature. It is also a method for making precise interfaces and material layers needed in superlattice structures and super-alloys. In thin-film applications, ALE allows excellent thickness uniformity over large areas. The process has primarily been developed for processing of compound materials. ALE is not only used to grow conventional thin films of II–VI wide-bandgap compounds [16.5,86,87], but is also a powerful method for the preparation of monolayers (ML) [16.88].

16.3 Bulk Crystal Growth

Bulk crystal is the most important subject studied in recent decades. The quality of bulk crystals is the most important aspect of electronic device design. To date, many growth methods have been developed to grow high-quality crystals. Significant improvements have been made in bulk crystal growth with regard to uniformity, reproducibility, thermal stability, diameter control, and impurity and dopant control. According to the phase balance, crystals can be grown from vapor phase, liquid (melt) phase, and solid phase.

16.3.1 The CVT and PVT Techniques

Crystal growth from the the vapor phase is the most basic method. It has advantages that growth can be performed at lower temperatures. This can prevent from phase transition and undesirable contamination. Therefore, this method has commonly been used to grow II–VI compound semiconductors.

Crystal growth techniques from the vapor phase can be divided into chemical vapor transport (CVT) and

physical vapor transport (PVT). CVT is based on chemical transport reactions that occur in a closed ampoule having two different temperature zones. Figure 16.6 shows a typical schematic diagram of the CVT technique. In the high-temperature region, the source AB reacts with the transport agent X:

In the low-temperature region, the reverse reaction takes place. The whole process continues by back-diffusion of the X_2 generated in the lower-temperature region. The transport agent X usually employed is hydrogen (H_2), a halogen (I_2 , Br_2 , Cl_2), a halide (HCl , HBr), and so on. For example, I_2 has been used as a transport agent for ZnS, ZnSe, ZnTe and CdS [16.89]; HCl , H_2 , Cl_2 , NH_3 [16.90], and C and CH_4 [16.91] have been used as the transport agents for ZnO. According to [16.89]: the typical growth temperature for ZnS is 1073–1173 K, for ZnSe 1023–1073 K, for ZnTe 973–1073 K; ΔT is 5–50 K; the concentration of the transport agent is

Fig. 16.6 Diagram of a conventional chemical vapor transport system

0.5–5 mg/cm³ of the ampoules vapor space; the aspect ratios are 5–17 at ampoule diameters of 10–20 mm. According to [16.91]; the growth temperature for ZnO is 1228–1273 K, and ΔT is 5–10 K. The transport rate does not strongly depend on the initial amount of carbon when the concentration of the transport agent is over 0.3 mg/cm³.

The PVT method is similar to CVT, but the transport agent is not used. This technique is based on the dissociative sublimation of compounds. Initially, the Piper–Polich method was developed, in 1961 [16.92]. Prior [16.93] improved the PVT method using a reservoir to control the deviation from stoichiometry; the experimental arrangement is shown in Fig. 16.7. The constituent element is placed in the reservoir. The reservoir temperature can be calculated according to the solid–vapor equilibrium

The total pressure (p) in ampoule is given by

$$\begin{aligned} p &= p_A + p_{B_2} \\ &= p_A + K \cdot p_A^{-2} \\ &= (K/p_{B_2})^{1/2} + p_{B_2} , \end{aligned} \quad (16.3)$$

where p_A and p_{B_2} are the partial pressures of the group II and VI elements respectively and $K = p_A^{-2} \cdot p_{B_2}$ is the equilibrium constant of (16.2). At any temperature, there is minimum total pressure (p_{\min}), which corresponds to the condition,

$$p_A = 2p_{B_2} = 2^{1/3} K^{2/3} . \quad (16.4)$$

Under this condition, the vapor-phase composition is stoichiometric and growth rate is maximum [16.94]. After modifying this method to use a closed ampoule, it was applied to grow high-purity and high-quality crystals of II–VI compounds.

Fig. 16.7 Diagram of the physical vapor transport Piper–Polich method

The **PVT** of II–VI compounds takes advantage of the volatility of both components of the compound semiconductor. This same volatility, coupled with typically high melting points, makes melt growth of these materials difficult. In the **PVT** process, an ampoule containing a polycrystalline source of the desired II–VI compound is heated to a temperature that causes the compound to sublime at a rate conducive to crystal growth. The ampoule is typically placed in a furnace having a temperature gradient over the length of the ampoule, so that the polycrystalline source materials sublime at the end with the higher temperature. The end of the ampoule where the crystal is to be grown is then maintained at a lower temperature. This temperature difference causes supersaturation, and vaporized molecules from source materials eventually deposit at the cooler end. In order to control the deviation from stoichiometry, a reservoir is often used (Fig. 16.7). One of the constituent elements is placed in it. By selecting the proper growth conditions, the rate of deposition can be set to a value leading to growth of high-quality crystals. Typically, **PVT** growth of II–VI compounds is carried out at temperatures much lower than their melting points; this gives benefits in terms of reduced defects, which are related to the melt growth of II–VI compounds such as voids and/or inclusions of excess components of the compound, and also helps to reduce the contamination of the growing crystal from the ampoule. Other effects, such as the reduction of point defects, are also typically found when crystals grown by **PVT** are compared to crystals grown by melt techniques. Although claims have been made that the lower temperatures of physical vapor transport crystal growth should also reduce the twinning found in most of the cubic II–VI compound crystals, the reduction is not usually realized in practice. The assumption that the twinning is a result of cubic/hexagonal phase transitions is not found to be the determining factor in twin formation.

Ohno et al. [16.95] grew cubic ZnS single crystals by the iodine transport method without a seed. By means of Zn-dip treatment, this low-resistivity crystal was used for homoepitaxial **MOCVD** growth, and a metal–insulator–semiconductor(MIS)-structured blue **LED**, which yielded an external quantum efficiency as high as 0.05%. They found that crystal quality was significantly improved by prebaking the ZnS powder in H₂S gas prior to growth. The growth rate also increased by three times.

Isshiki et al. [16.96] purified zinc by a process consisting of vacuum distillation and overlap zone melt-

ing in pure argon. Using refined zinc and commercial high-purity Se, high-quality ZnSe single crystals were grown by the same method, as reported by *Huang and Igaki* [16.97]. The emission intensities of donor-bound exciton (I₂) are remarkably small. The emission intensities of the radiative recombinations of free excitons (E_X) are very strong [16.98]. These intensities indicated the crystal had a very high purity and a very low donor concentration, and they suggest that the purity of the grown crystal strongly depends on the purity of the starting materials. This method is suitable for preparing high-purity crystals, since a purification effect is expected during growth. Impurities with a higher vapor pressure will condense at the reservoir portion and those with a lower vapor pressure will remain in the source crystal. This effect was confirmed by the **PL** results [16.99]. As for these crystals, photoexcited cyclotron resonance measurements have been attempted and cyclotron resonance signals due to electrons [16.100] and heavy holes [16.101] have been detected for the first time. The cyclotron mobility of electrons under $B = 7$ T is 2.3×10^5 cm²/Vs. This indicates that the quality of the grown crystals is very high. Furthermore, the donor concentration in the crystal is estimated to be 4×10^{14} cm³ by analyzing the temperature dependence of the cyclotron mobility [16.99].

The crystals are grown in a self-seeded approach by the **CVT** or **PVT** techniques introduced above. This limits single-crystal volume to several cm³. Meanwhile, grain boundaries and twins are easy to form during growth. In order to solve these problems, seeded chemical vapor transport (**SCVT**) and seeded physical vapor transport (**SPVT**), the so-called modified Lely method, have been developed [16.102]. The difference between **SCVT/SPVT** and **CVT/PVT** is that a seed is set in the crystal growth space before growth starts. The most successful method of eliminating twin formation has usually been by using a polycrystal or single-crystal seed. Even this seeding cannot assure complete elimination of twinning unless seeding is done carefully. The usual method of using small seeds and increasing the diameter of the growing crystal are dependent on the preparation and condition of the walls of the ampoule and the furnace profiles required to eliminate spurious nucleation from the walls. Since the use of a seed crystal provides better control over the nucleation process, high-quality single crystals can be grown [16.103, 104]. Using this technique, sizable single crystals of II–VI wide-bandgap compounds has been commercialized.

Fujita et al. [16.105] grew ZnS single crystals as large as 24 mm × 14 mm × 14 mm by the **SCVT** method

using iodine as a transport agent. The average linear growth rate was about 10^{-6} cm/s. The crystal size depended strongly on the ampoule geometry and the temperature difference between the seed and solvent. The study of the electrical properties showed that the annealed crystal was n-type.

16.3.2 Hydrothermal Growth

The hydrothermal technique is a method for growing crystal from aqueous solvent [16.106]. Figure 16.8 shows a diagram of hydrothermal techniques. The hydrothermal method of crystal growth has several advantages: (1) due to the use of a closed system, it is easier to control oxidization or maintain conditions that allow the synthesis of phases that are difficult to attain by other methods, such as compounds of elements in oxidation states, especially for transition-metal compounds; (2) crystal grow occurs under lower thermal strain, and thus may contain a lower dislocation density than when

the crystal is grown from a melt, where large thermal gradients exist; (3) the method has proven to be very useful for the synthesis of the so-called low-temperature phases; (4) it can be employed for large-scale synthesis of piezoelectric, magnetic, optic, ceramic, and many other special materials; (5) hydrothermal synthesis results in rapid convection and very efficient solute transfer, which results in comparatively rapid growth of larger, purer, and dislocation-free crystals. The most successful example of obtaining II–VI compounds is growing single ZnO crystals.

ZnO crystals are considered extrinsic n-type piezoelectric semiconductors. Undoped crystals have a typical resistivity of $0.1\text{--}100\ \Omega\text{ cm}$ and a drift mobility of $10\text{--}125\text{ cm}^2/\text{Vs}$. Low carrier concentrations can be approached by special growth and annealing methods. ZnO crystal is quite transparent in the range $0.4\text{--}6.0\ \mu\text{m}$. Slight absorption is sometimes found around $2.2\text{--}2.3\ \mu\text{m}$ and an additional slight absorption is found at $3.42\ \mu\text{m}$. Since 1953, Walker [16.107] and

Fig. 16.8 Diagram of a typical hydrothermal technique for growing ZnO single crystals

Fig. 16.9a,b Scheme of the vertical Bridgman growth system (a), and its temperature profiles (b)

many other researchers [16.108–111] have grown large ZnO single crystals with hydrothermal techniques and other methods.

The seed, suspended by a Pt wire, and sintered ZnO strings as a source material (nutrient), together with a KOH (3M) and LiOH (1M) aqueous solution, were put into a Pt crucible [16.112] (the hydrothermal conditions are different in different papers). The seed crystals and the source material were separated by a Pt baffle. The crucible was sealed by welding and put into an autoclave. This hydrothermal autoclave is made of high-strength steel. Then, the autoclave was put into a vertical furnace. The temperature of the autoclave was raised to about 673 K, which produced 0.1 GPa of pressure. the growth temperature was monitored by a thermocouple inserted in the autoclave. Seed crystals grew to about 10 mm or bigger after two weeks. The crystal habit of hydrothermal ZnO crystals grown on basal plane seeds shows that growth direction in [0001] is faster 3 times than [000 $\bar{1}$] [16.113].

16.3.3 Bridgman and Gradient Freezing (GF) Method

From the viewpoint of industrial production, melt growth is the most useful for obtaining large single crystals. VPE growth has limitations with regard to crystal size and productivity. The Bridgman technique is a typical crystal growth method from melt. Bridgman growth can be simply understood in terms of a molten charge that passes through a temperature gradient at

a slow speed and solidifies when the temperature is below the melting point of this material. If the ampoule and furnace are stationary and the temperature is gradually reduced by keeping the temperature gradient at the interface constant, this growth process is called the gradient freezing (GF) method [16.114]. In Bridgman or GF growth, single crystals can be grown using either seeded or unseeded ampoules or crucibles.

The Bridgman method has been most extensively used to grow II–VI wide-bandgap compounds such as CdTe, ZnTe and ZnSe crystals, because of the simplicity of the growth apparatus, the high growth rate and the availability of crystals of appropriate size and quality. There are two Bridgman method techniques: the high-pressure technique [16.115] and the closed technique [16.116]. In the former, it is inevitable that a compositional deviation from stoichiometry occurs during melting. Since the properties and structural perfection of these compound crystals are correlated very strongly with this nonstoichiometry [16.117], compositional deviation must be controlled during melt growth. *Omino et al.* [16.116] and *Wang et al.* [16.118, 119] have adopted a closed double crucible to prevent deviation of the melt from stoichiometric composition during Bridgman growth. Figure 16.9 shows a closed vertical Bridgman growth furnace and its temperature profiles.

In Bridgman growth, the temperature gradient (G) and growth rate (R) are very important parameters since they determine the shape of the solid–liquid interface. For this reason, the relationship between temperature gradient and growth rate is investigated. The experi-

Fig. 16.10 Relationship between growth velocity and temperature gradient at the growth interfaces

Fig. 16.11 Photograph of twin-free ZnSe single crystal grown by the vertical Bridgman technique

mental results are summarized in Fig. 16.10 [16.120, 121]. The experimental results show that, to grow a ZnSe single crystal, it is necessary that the G/R [(temperature) gradient/(growth) rate] value should be limited to $57\text{--}175\text{ K h/cm}^2$. The most suitable value of G/R , assessed from the determined optimum temperature gradient and growth rate, is 83 K h/cm^2 . Wang et al. [16.118, 119] found the optimum conditions to include: a special temperature program for removing the gas bubbles generated in melt, an overheating temperature of 76 K from the melting point of 1797 K , a temperature gradient of 30 K/cm and a growth rate of 3.6 mm/h as marked by the open squares in Fig. 16.10. Under these growth conditions, twin-free high-quality ZnSe single crystals (Fig. 16.11) were grown using a polycrystalline seed. Chemical etching on the cleaved (110) plane revealed that the average value of the etch pit density (EPD) is about $2 \times 10^5\text{ cm}^{-2}$. The rocking curves of four-crystal XRD showed a full-width at half-maximum (FWHM) value of 19 arcs. The resolved intensive free-exciton, bound-exciton emission

lines and the weak donor-acceptor-pair (DAP) emission bands are observed in the PL spectra at 4.2 K . The FWHM of the I_1^d emission was smaller than 0.5 meV . On the other hand, the deep-level emission bands were almost not observed. All these results suggest that the ZnSe single crystals grown by this method are of very high quality.

Asahi et al. [16.122] successfully grew ZnTe single crystals with a diameter of 80 mm and a length of 50 mm by the vertical gradient freezing (VGF) method. In this method, a high-pressure furnace was used and the melt was encapsulated by B_2O_3 during crystal growth. The growth direction was nearly $\langle 111 \rangle$ or $\langle 110 \rangle$. When long ZnTe crystals were grown, polycrystals were found at the tail. It seems to be difficult to grow an ingot longer than 50 mm . The researchers believed that this is because the shape of the solid-liquid interface easily becomes concave against the liquid at the tail owing to the low thermal conductivity of ZnTe. Evaluation of the crystals showed that the FWHMs of the rocking curve measured by XRD were about 20 arcs, and the EPDs were $5 \times 10^3\text{--}1 \times 10^4\text{ cm}^{-2}$.

16.3.4 The Traveling Heater Method (THM)

The traveling heater method (THM) [16.123] is a solution growth process whereby polycrystalline feed material with an average constant composition is progressively dissolved under the influence of a temperature gradient, followed by deposition in single-crystal form onto a seed with the same composition. The growth proceeds by the relative translation of the heater and charge. THM is particularly useful for the growth of binary and ternary semiconductor alloys, such as CdTe and CdZnTe [16.124]. In such materials, the wide separation between the solidus and liquidus in the pseudo-binary (CdTe–ZnTe) phase diagram imposes a monotonic variation in composition of the solid in the melt growth processes. The THM process ensures a constant macroscale composition in the crystal grown. Since the process takes place at a temperature below the melting point, contamination from the container is also reduced. The reduced operating temperature also leads to a lower ambient pressure within the growth environment, and a reduced risk of ampoule fracture.

16.3.5 Other Methods

Besides the growth methods described, there are many other techniques for growing single crystals of II–VI

Table 16.3 Growth methods for films and bulk crystals of wide-bandgap II–VI compounds

wide-bandgap compounds. Zone melting [16.125] and solid-state recrystallization (SSR) [16.126] are often used to grow bulk crystals of ZnSe, ZnS and CdTe.

Recently, *Asahi* et al. [16.127] proved that B_2O_3 is a suitable encapsulant for ZnTe melt growth. Furthermore, B_2O_3 and a total weight of 6N Zn and Te was charged into a pBN crucible. Then this crucible was put into a high-pressure furnace with five heaters. A ZnTe seed was used to pull the ZnTe crystal. Before growth started, the starting materials were heated to 1573 K and kept at this temperature for several hours. The pressure in the growth furnace was kept at 1.5–2 MPa using Ar gas during growth. The temperature gradient on the solid–liquid surface was about 10–20 K/cm. The growth rate was 2–4 mm/h. Under these growth conditions, ZnTe single crystals with a diameter of 80 mm and a height of 40 mm were successfully grown using a combined GF/Kyropoulos method [16.127] (Fig. 16.12).

Some growth methods for film and bulk crystals are summarized in Table 16.3.

**Fig. 16.12** ZnTe single crystal grown by a combination of the GF and Kyropoulos methods

16.4 Conclusions

It was expected that II–VI wide-bandgap compounds would become applicable to optoelectronic devices, especially LEDs and LDs in the short-wavelength visible-light region. However, as they are very strongly bonded with a nearly equal balance of covalent and ionic bonding, it is challenging to grow high-purity high-quality single crystals. Another problem with their application to devices is the difficulty of controlling the conductive type. This is because native defects commonly occur in these semiconductors. These native defects can have either a donor or acceptor character, or even be amphoteric, and they act as compensating

centers. Furthermore, these defects react with dopant impurities to form complexes. This makes it difficult to reverse the conductive type. For example, in the case of ZnSe, it is still difficult to obtain low-resistivity p-type crystals or epilayers that can be used to fabricate devices. Therefore, a significant improvement in the understanding of the fundamental physical and chemical properties needs to be achieved. In particular, the specifications for many applications are very demanding, and considerable progress needs to be made in growth, particularly in the areas of reproducibility, convenient shape, conductivity, and structural perfection.

Structural Ch

17. Structural Characterization

The aim of this chapter is to convey the basic principles of X-ray and electron diffraction, as used in the structural characterization of semiconductor heterostructures. A number of key concepts associated with radiation–material and particle–material interactions are introduced, with emphasis placed on the nature of the signal used for sample interrogation. Various modes of imaging and electron diffraction are then described, followed by a brief appraisal of the main techniques used to prepare electron-transparent membranes for TEM analysis. A number of case studies on electronic and photonic material systems are then presented in the context of a growth or device development program; these emphasize the need to use complementary techniques when characterizing a given heterostructure.

17.8 Concluding Remarks	370
References	370

The functional properties of semiconductors emanate from their atomic structures; indeed, the interrelationship between materials processing, microstructure and functional properties lies at the heart of semiconductor science and technology. Therefore, if we are to elucidate how the functional properties of a semiconductor depend on the processing history (the growth or device fabrication procedures used), then we must study the development of the microstructure of the semiconductor by applying an appropriate combination of analytical techniques to the given bulk crystal, heterostructure or integrated device structure.

The main aim of this chapter is to provide a general introduction to the techniques used to characterize the structures of semiconductors. Thus, we consider techniques such as X-ray diffraction (XRD) and electron diffraction, combined with diffraction contrast imaging, alongside related techniques used for chem-

ical microanalysis, since modern instruments such as analytical electron microscopes (AEMs) provide a variety of operational modes that allow both structure and chemistry to be investigated, in addition to functional activity. For example, chemical microanalyses of the fine-scale structures of materials can be performed within a scanning electron microscope (SEM) and/or a transmission electron microscope (TEM), using the techniques of energy dispersive X-ray (EDX) analysis, wavelength dispersive X-ray (WDX) analysis or electron energy loss spectrometry (EELS). In addition, electrical and optical properties of semiconductors can also be investigated in situ using the techniques of electron beam induced conductivity (EBIC) or cathodoluminescence (CL), respectively. Techniques such as X-ray photoelectron spectrometry (XPS; also known as electron spectroscopy for chemical analysis, ESCA), secondary ion mass spectrometry (SIMS) or Ruther-

ford backscattering spectrometry (RBS), can also be used to study semiconductor chemistry. We should also mention reflection high-energy electron diffraction (RHEED), which can be used for the rapid structural assessment of the near surface of bulk or thin film samples.

A far from exhaustive list of acronyms one might come across when assessing a given sample is incorporated into the general list of abbreviations at the start of this book. We can organize these techniques used to characterize materials into groups based on a number of viewpoints: for example, with respect to the material property being investigated; whether they are destructive or nondestructive; bulk or near-surface assessment techniques; based on radiation–material or particle–material interactions, or based on elastic or inelastic scattering processes, or whether they are diffraction-, imaging- or spectroscopic-based techniques.

In this broad introduction to the structural characterization of semiconductors, we focus on the interaction of

a material with radiation and/or particles. Thus, we start by considering the interactions of photons, electrons or ions with a sample and the nature of the signals used for structural or chemical microanalysis. We then briefly focus on the techniques of X-ray and electron diffraction, and issues regarding the formation of TEM images. The aim is simply to convey an appreciation of the underlying principles, the applicability of these characterization techniques and the information provided by them. We also briefly consider sample preparation, and the chapter closes with a variety of TEM-based case studies of semiconductor heterostructures, which are included to illustrate some of the approaches used to characterize fine-scale microstructure, as well as to emphasise the need for complementary analysis when assessing the interrelationships between processing, structure and functional properties. Much literature already exists in this area, and a selection of references is provided at the end of the chapter that tackle many of the topics we cover here in more detail [17.1–15].

17.1 Radiation–Material Interactions

Each part of the electromagnetic spectrum has quantum energies that can be used to elicit certain forms of excitation at the atomic or molecular level. Different parts of the electromagnetic spectrum will interact with matter in different ways, according to the energy states within the material, allowing absorption or ionization effects to

occur. The salient features of these various radiation–material interaction processes are summarized in the schematics shown in Fig. 17.1.

As the quantum energy increases from radio waves, through microwaves, to infrared and visible light, absorption increases, whilst specific quantized ionization effects come into play upon moving further into the ultraviolet and X-ray parts of the spectrum. Microwave and infrared radiation, for example, can interact with the quantum states of molecular rotation and torsion, leading to the generation of heat for example. Strong absorption also occurs within metallic conductors, leading to the induction of electric currents. Visible and ultraviolet light can elevate electrons to higher energy levels in what is known as the photoelectric effect, which is essentially the liberation of electrons from matter by short-wavelength electromagnetic radiation when all of the incident radiation energy is transferred to an electron. This process can be explained in terms of the absorption of discrete photon energies, with electrons being emitted when the photon energy exceeds the material's work function for the case of weakly bound electrons or the binding energy for more strongly bound inner shell electrons (Fig. 17.2a).

X-ray and γ -ray quantum energies are generally too high to be completely absorbed in direct electron

Fig. 17.1 Schematic illustrating the various interactions of energetic radiation with a molecule or atom

Fig. 17.2a–c Schematics illustrating (a) the photoelectric effect; (b) characteristic X-ray emission and (c) Auger electron emission

transitions, but they can induce ionization, with the displacement of electrons from atoms to form ions. The relaxation of a high-energy electron to the vacated state can lead to the emission of a characteristic X-ray (Fig. 17.2b) or the emission of an Auger electron (Fig. 17.2c). During the process of ionization, some of the incident pho-

ton energy is transferred to the ejected electron in the form of kinetic energy, and the scattering of a lower energy photon (longer wavelength X-ray) occurs, termed Compton scattering. X-rays can also be scattered elastically by shell electrons, without the loss of energy, through a process of absorption and re-emission.

17.2 Particle–Material Interactions

The interaction of an energetic particle with the surface of a material is most commonly associated with the process of sputtering – the non-thermal removal of atoms from a surface under ion bombardment. Transfer of momentum to the surface atoms is followed by a chain of collision events leading to the ejection of matrix atoms. Figure 17.3 illustrates the various signals produced when a particle interacts with a material, depending on the energy available. In broad terms, processes in the range 10^4 – 10^5 eV are associated with ion implantation, the 10 – 10^3 eV energy range is associated with sputtering, whilst the creation of activated point defects occurs in the 1 – 10^3 eV range. At lower 0.1 – 100 eV energies, desorption of surface impurity atoms occurs, whilst energies in the range 0.01 – 1 eV are associated with the enhanced

mobility of surface condensing particles, such as those required during growth. In practical terms, the process of sputtering is most efficient when the masses of the incident and ejected particles are similar, whilst it is also dependent on the sputtering gas pressure, the energy spread of the particles, the bias conditions and the sample geometry.

In this context, we should briefly mention the technique of SIMS, which uses heavy ions, typically in the range 2 – 30 keV, with an ion current density of ≈ 1 mA/cm². The sputtered atoms consist of a mixture of neutrals and ions, and the latter may be mass-spectrally analyzed in order to perform elemental depth profiling. The sensitivity of the technique is very high – for example on the scale of dopant concentrations

Fig. 17.3 Schematic illustrating the signals produced by the interaction of an energetic ion beam with a sample

within semiconductors – but standards are required for quantitative analysis. One variant of **SIMS** makes use of lower energy primary ions ($0.5\text{--}2\text{ keV}$, $\approx 1\text{ nA/cm}^2$) with an almost negligible sputter rate, thus enabling surface chemical analysis. Conversely, the technique of **RBS** makes use of a very high energy ($2\text{--}3\text{ MeV}$) beam of light ions bombarding a sample normal to its surface. An ion such as helium is chosen to avoid the effects of sputtering, whilst high energy is required to overcome the problem of ion neutralization and the screening interaction potential between the ion and the nucleus associated with techniques such as low-energy ion scattering (**LEIS**). As an energetic positive ion penetrates the sample it loses energy, mainly due to collisions with electrons, but occasionally (and more significantly) with

nuclei. The energy of the backscattered ion depends on the depth of the collision and the mass of the target atom. By measuring the energy spectrum of the recoiling ions, information on elemental composition and depth within a sample can be obtained.

By way of comparison, Fig. 17.4 illustrates the variety of signals produced from the interaction of an energetic beam of electrons with a thin semiconductor sample. In order to make sense of the origins of the many different signals, we must consider the phenomenon of electron scattering, which underpins them all. The process of elastic (Rutherford) scattering arises from an electrostatic (Coulomb) interaction with the nucleus and surrounding electrons of an atom, leading to a change in the incident electron direction without loss of energy. Elastically scattered electrons contribute to the formation of diffraction patterns and diffraction contrast images in **TEM**. Conversely, inelastically scattered electrons have, by definition, lost a certain amount of energy. In this context, core-shell interaction processes produce scattered electrons whose energies depend on the atomic number of the scatterer, and an analysis of the loss of electron energy (up to $\approx 1000\text{ eV}$) is the basis of the technique of electron energy loss spectroscopy (**EELS**). In addition, plasmon scattering ($5\text{--}30\text{ eV}$ loss) can occur, due to the interactions of incident electrons with waves in the conduction band of a metal, or the bonding electrons of non-metals. The signatures from plasmon-scattered electrons can dominate the low-energy regimes of **EELS** spectra, providing information on sample thickness. Phonon scattering ($\approx 1\text{ eV}$ loss) can also occur, which is the interaction of incident electrons with quantized atomic vibrations within a sample, leading to the production of heat. In an interaction of an electron beam with a bulk sample, nearly all of the incident energy ends up being dissipated through such phonon interactions. The probability of each type of scattering interaction is commonly expressed either as a cross-section, representing the apparent area the scattering process presents to the electron, or as a mean free path, which is the average distance the electron travels before being scattered.

A variety of secondary events also occur as a direct consequence of these primary electron scattering processes. For example, following interactions with a high-energy beam of electrons, excited atoms may subsequently relax in a number of different ways (in a similar fashion to the processes induced by incident high-energy X-ray photons). If core-level (inner shell) electrons are displaced, the relaxation of electrons from higher energy shells to the lower energy core states can

Fig. 17.4 Schematic illustrating the signals produced by the interaction of an energetic electron beam with a thin sample foil

Table 17.1 Overview of characterization techniques

Technique	Primary beam	Energy	Signals detected	Assessment	Spatial resolution	Elements detected	Detection limit
AES	Electron	0.5–10 keV	Auger electron	Surface composition	lateral \approx 200 nm (LaB ₆ source) lateral \approx 20 nm (FE source) depth \approx 2–20 nm	Li–U	\approx 0.1–1 at % (sub-monolayer) accuracy \approx 30% \approx 0.001–10 at %

lead to the discrete emission of X-ray photons characteristic of the atomic number of the element concerned. This is referred to as the K, L, M, N series, and Moseley's law states that the square root of the frequency of the characteristic X-rays of this series, for certain elements, is linearly related to the atomic number. Discrimination of these characteristic X-rays, as a function of energy or wavelength, provides the basis for the EDX or the WDX techniques, respectively. Alternatively, a secondary process of Auger electron emission may again occur, particularly for low atomic number materials, whereby outer electrons are ejected with a characteristic kinetic energy. It should also be noted that characteristic X-rays may also induce the emission of lower energy X-rays within a sample, and this is the basis of X-ray fluorescence (XRF) and the origin of background scintillation during EDX analysis.

In addition, if an outer (valence) electron state is vacant, relaxation across the band-gap of a semiconductor may occur with the emission of light, and this

constitutes the basis of the CL technique. Alternatively, a current may be induced within a sample and non-radiative recombination pathways in the presence of structural defects (and a collection junction) provide the contrast mechanism for the EBIC technique that profiles the electrical activity within a crystalline semiconductor. Also, incident electrons that interact with atomic nuclei may become backscattered with energies comparable to the incident energy, and used to image a sample surface with a contrast that is dependent on the average local composition. Secondary (low-energy, < 50 eV) electrons (SEs), produced by a variety of mechanisms, may also be emitted and escape from the near-surface of a sample. SEs can be used to obtain topographic images of irregular surfaces since they are easily absorbed.

Table 17.1 lists the most commonly used characterization techniques based on X-ray, ion or electron beam interactions with a semiconductor, and broadly indicates their limits of applicability.

17.3 X-Ray Diffraction

The basic concepts behind radiation–material interactions and scattering link into the concept of diffraction, whereby the spatial distribution and intensity of scattered X-rays or electrons provide information on the arrangement of atoms in a periodic sample. The theory of wave–particle duality proposes that an electron may be considered to be a wave rather than a particle when

discussing diffraction. Electrons are scattered by electric fields within a crystal whilst X-rays are scattered by shell electrons. Nevertheless, the geometry of diffraction is very similar in both cases, being governed by Bragg's law.

The basic principles associated with diffraction (in reflection, transmission or glancing angle geometry) are generally introduced with reference to X-ray scattering and interference. X-rays are a form of energetic electromagnetic radiation of wavelength $\approx 10^{-10}$ – 10^{-11} m, of comparable size to the spacing of atoms within a solid. A crystal lattice comprises a regular array of atoms; the electron clouds around these act as point sources for spherical X-ray wavelets, through a process of absorption and re-emission, when interaction with an incident beam of X-ray occurs. Constructive interference of the scattered wavelets, termed the Huygens's principle (Fig. 17.5), occurs in preferred directions, depending on the Bravais lattice of the crystal and the X-ray wavelength. The positions of the resultant maxima in scattering intensity may be used to deduce crystal plane spacings and hence the structure of an unknown sample. Geometrical considerations show that the scattering angles corresponding to diffracted intensity maxima can be described by the Bragg equation $n\lambda = 2d \sin \theta$ (sometimes expressed as $\lambda = 2d_{hkl} \sin \theta_{hkl}$). Formally,

Fig. 17.5 Schematic illustrating Huygens's principle, with a reconstruction of spherically emitted X-ray wavefronts providing diffracted intensity in specific directions

Fig. 17.6 Geometric illustration of Bragg diffraction. For constructive interference, $n\lambda = AB + BC = 2d \sin \theta$

this equation describes the minimum condition for the coherent diffraction of a monochromatic X-ray beam from a set of planes of a primitive lattice. Figure 17.6 illustrates the geometrical conditions associated with Bragg diffraction from a set of $\{hkl\}$ planes spaced d_{hkl} apart, with X-rays incident at a Bragg angle θ being diffracted through an angle 2θ . The path difference between the X-rays ‘reflected’ from successive planes must be equivalent to an integer number of wavelengths n for constructive interference to occur.

In order to interpret the information contained in the *intensity* of the diffracted beam, which is measured in practice, it is necessary to consider the amplitude of the elastically scattered waves. (The phase of the scattered beam is much more difficult to measure.) A useful concept to introduce at this stage is that of the atomic scattering factor, f , which is a measure of the amplitude of the wave scattered by an atom, which depends on the number of electrons in the atom. Formally, the atomic scattering factor is the ratio of the amplitude of the wave scattered by an atom to the amplitude scattered in the same direction by a free classical electron. (For the purpose of such discussions, an electron orbiting an atom is considered to be a free classical electron.) The scattered amplitude (and hence intensity) varies with direction, with higher angles θ having lower amplitudes.

When X-rays interact with a periodic crystal lattice, it is considered that each atom scatters with an amplitude f into an hkl reflection, while there is a summation of all of the scattering amplitudes from different atoms, with phase differences that depend on hkl and the relative positions of the atoms. This leads to the concept of the structure factor, F_{hkl} , which is the total scattering amplitude from all of the atoms in one unit cell of a lattice. Formally, the structure factor is the ratio of the amplitude scattered by a unit cell into an hkl reflection to that scattered in the same direction by

a free classical electron. The phase difference between waves scattered from two different atoms depends on the Miller indices of the reflection being considered and the fractional coordinates of the atoms within the unit cell. In general terms, for a reflection from a set of $\{hkl\}$ planes, the phase difference ϕ between the wave scattered by an atom at the origin and that scattered by an atom with fractional coordinates x, y, z is given by $\phi = 2\pi(hx + ky + lz)$. In theoretical terms, the resultant intensity of the scattered beam is denoted $I_{hkl} \propto |F_{hkl}|^2$, where $F_{hkl} = \sum f_j(\theta) \exp(i\phi_j)$, which is a summation of the individual scattered sinusoidal waves, performed over both phase and amplitude. In a practical diffraction experiment, however, the combination of photoionization and Compton scattering can act to diminish the scattered beam intensity. Consideration also needs to be given to the effects of absorption, along with the effect of multiplicity, which arises from the number of symmetrical variants of a unit cell, and the geometrical and polarization factors specific to a given experimental arrangement.

The crystallographic structure of an unknown material can, nevertheless, be analyzed via the diffraction of X-rays of known wavelength. For example, for a crystal system with orthogonal axes, the general formula which relates plane spacing, d_{hkl} , to the plane index $\{hkl\}$ and the lattice parameters a, b, c is $1/(d_{hkl})^2 = h^2/a^2 + k^2/b^2 + l^2/c^2$. For a cubic system, this simplifies to $d_{hkl} = a/\sqrt{(h^2 + k^2 + l^2)} = a/\sqrt{N}$. Thus, $\lambda = 2a \sin \theta / \sqrt{N}$, from which $N = (4a^2/\lambda^2) \sin^2 \theta$ and hence $N \propto \sin^2 \theta$. Accordingly, the 2θ angles of scattering arising from the process of X-ray diffraction may be used to identify values for N , against which hkl indices can be assigned and the lattice identified. Information is contained within the intensities and widths of the diffracted X-ray peaks, in addition to their positions. The process of formal identification can be automated by electronically referencing crystallographic databases containing the positions and relative magnitudes of the strongest diffraction peaks from known compounds. Systematic or partial absences may also occur depending on the lattice symmetry, and the intensities of some peaks may be weak due to the motif of the crystal lattice – the number of atoms sited on each lattice point. For example, sphalerite or wurtzite lattices may show weak reflections that are absent for face-centered cubic or hexagonal close-packed structures, respectively.

Partial differentiation of the Bragg equation gives $2(\sin \theta)\delta d + 2d(\cos \theta)\delta \theta = 0$, from which $\delta d/\delta \theta = -d \cot \theta$. Thus, for a fixed error in θ , the error in d_{hkl} will minimize as $\cot \theta$ tends to zero (as θ tends

Fig. 17.7 X-ray four-circle diffractometer

to 90°). Diffraction techniques are therefore more accurate when measurements are made at high 2θ angles. Similarly, it can be shown that the sensitivities and resolutions of diffraction measurements improve at high angles. The sensitivity of the X-ray diffraction technique, for example, is sufficiently high to enable subtle stress measurements to be made, with elastic changes in plane spacing leading to small shifts in diffracted peak positions. Accordingly, diffraction techniques may be used to investigate temperature-dependent order–disorder transitions within alloys and preferred orientation effects. The high accuracy of lattice parameter measurement similarly enables good compositional analysis of an alloy, for example by assuming Vegard’s law, that the alloy exhibits a linear dependence of lattice parameter on composition between the extremes of composition. Brief reference should be made here to the related technique of neutron diffraction, which is able to sample over a much larger range of d_{hkl} spacings, which makes it particularly useful for the *ab initio* determination of very complex structures. The very rigorous approach of Rietveld refinement can also be used to model a complete diffraction profile, deducing the structure from first principles using atom positions as fitted parameters.

The principle behind the generation of X-rays from characteristic transitions, used when performing chemical microanalyses of unknown samples by EDX or WDX, also provides the route to defining an X-ray source from a known target sample for the purpose of XRD. In practical terms, the X-ray tube of a diffrac-

tometer is an evacuated vessel in which electrons from a hot filament are focused onto a cooled metal target, such as Cu or Ni. The X-ray spectrum generated consists of X-rays characteristic of the target material, along with a background emission of X-rays of continuous wavelengths, termed Bremsstrahlung (braking radiation), which are caused by the acceleration of electrons in the vicinity of nuclei. The X-rays emerging from the tube, through a window made from a material of low atomic number, can be filtered and collimated to define a beam of specific wavelength.

The precise geometry used in a diffraction experiment will depend on the form of the sample and the information content required. For example, crystalline samples such as semiconductor heterostructures can be rotated within a cylindrical geometrical framework that enables successive sets of crystal planes to be brought into play for detection. Figure 17.7 illustrates the basic geometrical arrangements for a four-circle diffractometer that allows diffraction spectra to be acquired. Computer-controlled rotation of the sample around ω , χ and ϕ axes, as the detector is rotated about the 2θ axis, enables the positions and intensities of hkl reflections to be recorded. By way of example, Fig. 17.8 shows a $2\theta/\omega$ plot recorded from a heteroepitaxial GaN/GaAs(001) sample, with reflections attributable to both epilayer and substrate, whilst the full width at half maximum (FWHM) values for the diffraction peaks provide a measure of the mosaic spread of the subgrains within the sample.

Since amorphous materials do not exhibit long-range order, their diffraction profiles show diffuse intensities rather than well-defined maxima. Partially crystalline materials may show broad diffraction peaks, from which

Fig. 17.8 Example of a $2\theta/\omega$ plot for cubic GaN/GaAs(001)

it is possible to approximate the crystal size from the λ -peak-width relationship. Other X-ray diffraction techniques include Laue back reflection, that can be used conveniently to orient bulk single crystals, for example for sectioning prior to use as substrates for heteroepitaxial growth. Alternatively, the Debye–Scherrer method can be used for powder samples, since a significant number of crystal grains will always be in an orientation that satisfies the Bragg equation for each set of $\{hkl\}$ planes. In this scattering arrangement, the diffracted rays form cones coaxial with the incident X-ray beam, with each cone of diffracted rays corresponding to a Bragg reflection from a specific set of lattice planes in the sample. A cylindrical strip of photographic film can be used to detect the diffracted intensity.

To reiterate, it is the combination of Bragg's law and the structure factor equation that enables the directions and intensities of beams scattered from a crystal to be predicted. In this context, it is instructive to briefly compare XRD with electron diffraction. Electrons are scattered by the periodic potential – the electric field – within a crystal lattice, whilst X-rays are scattered by shell electrons. Since X-rays and electrons exhibit comparable and comparatively small wavelengths, respectively, on the scale of the plane spacings of a crystal lattice, this equates to large and small angles of scatter-

ing, respectively, for the diffracted beams. Accordingly, in principle XRD techniques offer greater accuracy than electron diffraction for the measurement of lattice parameters. It should also be noted that XRD is essentially a kinematic process based on single scattering events, whilst electron diffraction is potentially more complex due to the possibility of dynamic (or plural) scattering processes which can affect the generated intensities. Also, electrons are more strongly absorbed than X-rays, so there is need for very thin sample foils, typically $< 1\ \mu\text{m}$, for the purposes of transmission electron diffraction (TED) experiments. However, electrons are more easily scattered by a crystal lattice than X-rays, albeit through small angles, so an electron-transparent sample foil is capable of producing intense diffracted beams. X-rays require a much greater interaction volume to achieve a considerable diffraction intensity. The effectiveness of the technique of electron diffraction becomes most apparent when combined with TEM-based chemical microanalysis imaging techniques. This enables features such as small grains and embedded phases, or linear or planar defect structures such as dislocations and domain boundaries, to be investigated in detail.

Before describing some variants of the electron diffraction technique, a few concepts related to imaging and modes of operation of the TEM need to be introduced.

17.4 Optics, Imaging and Electron Diffraction

The aim of a microscope-based system is to image an object at high magnification, with optimum resolution and without distortion. The concepts of magnification and resolution associated with imaging in electron microscopy are usually introduced via light ray diagrams for optical microscopy. The constraints on achieving optimum resolution in TEM are generally considered to be lens aberration and astigmatism. The concepts of depth of field and depth of focus must also be considered.

If we consider the objective lens shown in Fig. 17.9, a single lens is characterized by a focal length f and a magnification M . The expression $1/f = 1/u + 1/v$ relates the focal length to the object distance u and the image distance v for a thin convex lens. The magnification of this lens is then given by $M = v/u = f/(u - f) = (v - f)/f$, from which it is apparent that $u - f$ must be small and positive for a large magnification to be obtained. In practice, a series of lenses are used to achieve a high magnification overall

whilst minimizing distortion effects. For the combined projection microscope system shown in Fig. 17.9, magnification scales as $M' = (v - f)(v' - f')/ff'$.

Resolution is defined as being the smallest separation of two points on an object that can be reproduced distinctly within an image. The resolution of an optical lens system is diffraction-limited since light must pass through a series of apertures, and so a point source is imaged as a set of Airy rings. Formally, the minimum resolvable separation of two point sources, imaged as two overlapping sets of Airy rings, is given by the Rayleigh criterion, whereby the center of one set of Airy rings overlaps the first minimum of the second set of Airy rings. The defining equation for resolution is given by $r = 0.61\lambda/n \sin \alpha$, where λ is the wavelength of the imaging radiation, n is the refractive index of the lens, and α is the semiangle subtended at the lens. The combined term $n \sin \alpha$ is the 'numerical aperture' of the lens. Thus, resolution can be improved by decreasing λ

Fig. 17.9 Schematic ray diagram for a transmission projection optical microscope

or by increasing n or α . It is noted that magnification beyond the resolution limit of the system is possible, but there is no benefit to achieving this, and so it is termed ‘empty magnification.’

The performance of a **TEM** can be described in analogous terms, comprising an electron gun and a series of electromagnetic lenses for sample illumination, image formation and magnification: the condenser, objective and projector systems, respectively (Fig. 17.10). The electron source can be either a hot filament (e.g. W or LaB₆) for thermionic emission, or a hot or cold cathode (e.g. ZrO₂ coated W) for field emission. The gun and lenses are traditionally assembled in a column with a viewing screen and camera at the bottom to record images or diffraction patterns from an electron-transparent sample placed within the objective pole piece. A range of differently sized apertures are located in the condenser system to help collimate the electron probe, in the projector system to select a region of sample from which a diffraction pattern may be formed, and in the objective lens just below the sample to se-

Fig. 17.10 Simplified lens configuration of a **TEM**

lect the transmitted beam(s) used to form an image. The path of travel of the electron beam through the entire electron-optic column must be under conditions of high vacuum, considering the ease of absorption of electrons in air. The electrons are accelerated by high voltage, typically 100 or 200 kV, although there are **TEMs** that operate at MV conditions, depending on the intended application. An accelerated, high-energy electron acquires significant kinetic energy and momentum. It can also be represented by a wavelength (corrected to take into account relativity) that can be approximated in nanometers by $\lambda = [1.5/(V + 10^{-6} V^2)]^{0.5}$. By way of example, an electron beam within a conventional **TEM** operating at 200 kV has a relativistically corrected wavelength of 0.0025 nm, as compared with the range of ≈ 400 –700 nm for visible light. Since resolution is wavelength-limited, the technique of **TEM** is, in principle, able to provide a vast improvement in resolution over conventional optical systems. The equation for resolution becomes approximated by $r \approx 0.61\lambda/\alpha$ since $n = 1$ for electromagnetic lenses and $\sin \alpha \approx \alpha$ in view of the small angles associated with electron diffraction. A value of $\alpha \approx 150$ mrad would suggest a resolution approaching ≈ 0.01 nm. However, this level of resolution for **TEM** is generally not achievable in practice due to the effect of lens aberration, which de-

Fig. 17.11a–c Schematic illustration of (a) spherical aberration; (b) chromatic aberration and (c) astigmatism

grades the resolution of an image to a ‘disc of least confusion’ above the theoretical wavelength-limited resolution of the electron-optic system. Resolution values of $\approx 0.2 \text{ nm} - 0.3 \text{ nm}$ are associated with the best conventional instruments. (When charting the historical development of TEM, improvements in resolution have depended on the construction of microscopes operating at higher voltages, in order to capitalize on the benefits from the reduced electron wavelength. However, it should be noted that recent improvements in techniques of compensating for spherical aberration have now enabled a resolution of $\approx 0.1 \text{ nm}$ to be achieved for intermediate-voltage, field emission gun instruments.)

The variation in focal length of a lens as a function of the distance of a beam from the center of the lens results in rays traveling further from the optic axis being brought to focus closer to the lens (Fig. 17.11a). This spread in path lengths of rays traveling from an object to the image plane is termed spherical aberration. In this case, the radius of the disc of least confusion is given by $r_s = C_s \alpha^3$, when referred back to the object, where C_s is termed the spherical aberration coefficient and α is again the semiangle, in radians, subtended at the lens. Spherical aberration can be limited by reducing α ; in other words by ‘stopping down’ the lens by using smaller apertures (in this case, the term α can be represented by a term β corresponding to the ‘aperture collection angle’). However, this conflicts with the large value of α needed to optimize resolution, so a balance is required for optimum resolution, which is achieved when $\alpha_{\text{opt}} \sim (\lambda/C_s)^{1/4}$, corresponding to an effective resolution of $r_{\text{opt}} \sim \lambda^{3/4} C_s^{1/4}$. Lenses also exhibit different focal lengths for electrons with different wavelengths; such a spread of wavelengths can arise from slight fluctuations in the accelerating voltage or from

inelastic scattering (energy loss) processes within the specimen, and this effect is termed chromatic aberration (Fig. 17.11b). The radius of the disc of least confusion in this instance is given by $r_c = C_c \alpha (\Delta E/E_0)$, where C_c is the chromatic aberration coefficient, E_0 the accelerating voltage and ΔE the spread in electron energy.

An additional aberration, termed astigmatism, arises from the asymmetry of a lens about the optic axis. The different focal lengths of a lens for different orientations leads to a loss of sharpness of the image at focus.

Fig. 17.12a,b Schematic ray diagrams showing the projection of a (a) diffraction pattern and (b) an image onto a TEM viewing screen

One measure of the astigmatism is the distance between the two foci formed at right angles along the optic axis (Fig. 17.11c), in contrast to a single point of focus. Astigmatism may be compensated for by using electromagnetic stigmators that generate a compensating field to bring the rays back into common focus. Distortion of an image can also occur due to slight variations in magnification with radial distance from the optic axis, leading to so-called ‘pin-cushion’ or ‘barrel’ distortion. This effect can become particularly noticeable at very low magnification.

The term ‘depth of field’ is defined as the distance along the optic axis that an object can be moved without noticeably reducing the resolution. This effect is again dependent on the radius of the disc of least confusion that can be tolerated and α . The depth of field approximates to λ/α^2 , and a typical value of a few tens of nm for electron microscopy means that every point within the thickness of a typical electron-transparent foil can be imaged at focus. Conversely, the ‘depth of focus’ corresponds to the maximum permissible spacing between the imaging screen and the photographic plate or CCD used to record an image. The depth of focus approximates to $\lambda M^2/\alpha^2$, and since this works out at many meters, the viewing screen and recording system of an electron microscope need not coincide.

Following on from these general considerations affecting the process of imaging, we now move on to briefly describe the conventional modes of operation of a TEM. The accelerating stack and condenser system of the microscope defines the high-energy electron probe incident at a thin sample, within which many complex interactions occur and various signals are produced, as detailed earlier. A diffraction pattern is initially formed in the back focal plane of the objective lens and the recombination of diffracted beams allows the reconstruction of an inverted image in the first image plane. Changing the strengths of the intermediate lenses allows the back focal plane (corresponding to a projection of reciprocal space) or image plane (corresponding to a projection of real space) to be observed on the viewing screen (Fig. 17.12a,b). Placing an aperture with a selected area located in an intermediate image plane around an area of interest within a projected image enables us to ensure that only beams from that particular area of the sample contribute to the diffraction pattern viewed on the screen.

It is sometimes convenient to think of the intersection of an Ewald sphere with a reciprocal lattice when describing the construction and projection of a diffraction pattern. A reciprocal lattice is constructed from

Fig. 17.13a–c Ewald sphere construction for (a) X-ray diffraction (large angle scattering); (b) electron diffraction (zone axis projection) and (c) electron diffraction (tilted projection)

a crystal lattice such that any vector from the origin to a diffracted spot is normal to a particular plane in the real lattice, with a reciprocal length given by the plane spacing. Thus, a three-dimensional crystal lattice can be transformed into a three-dimensional reciprocal lattice. The Ewald sphere can be thought of as a geometrical construction of radius $1/\lambda$ intersecting the reciprocal lattice. Figure 17.13a illustrates the construction of an Ewald sphere for the case of large-angle scattering (X-ray diffraction). The direction of the incident beam at the sample corresponds to the direction of the radius of the Ewald sphere, and the point of emergence of this vector at the sphere surface coincident with a reciprocal lattice point is taken as the origin of the spectrum or diffraction pattern. The same construction applies for a beam of electrons, but the sphere surface has a very shallow curvature relative to the reciprocal lattice spacing, due to the very small value of λ relative to d_{hkl} (Fig. 17.13b). Also, diffraction from a thin crystal is associated with a lengthening of the reciprocal lattice spots into rods in a direction parallel to the electron beam.

Consequently, if the electron beam is incident along a low index zone axis, the Ewald sphere approximates to a plane and intersects a layer of reciprocal lattice points, and a two-dimensional array of diffraction spots is projected. In very general terms, it is considered that a set of $\{hkl\}$ planes is at the Bragg condition when the reciprocal lattice point corresponding to hkl falls on the surface of the Ewald sphere. For the case of large angles of diffraction, an outer ring of diffraction spots may be observed, termed a high-order Laue zone (HOLZ), since the Ewald sphere has sufficient curvature to intersect with a neighboring layer of points within the reciprocal lattice (Fig. 17.13c).

We should also mention the Kikuchi lines that arise in diffraction patterns due to the elastic scattering of incoherently scattered electrons. The intensities of these Kikuchi lines increase with increasing thickness of the sample foil, and the line spacings are the same as the spacings of the diffraction spots from the associated crystal planes. Kikuchi lines move as the sample is tilted and hence can be used to establish very precise crystal orientations for the purpose of image contrast or convergent beam electron diffraction (CBED) experiments.

Referring back to Fig. 17.12, a diffracted beam may be selected using an aperture inserted into the back focal plane of the objective lens and used to form an image. If the undeviated, transmitted beam is used, then a bright field image is formed where the areas that diffract strongly appear dark. Image contrast also arises from a mass-thickness effect, whereby thicker or high-density regions of material scatter more strongly and hence appear dark. Alternatively, centered dark field images can be created by aligning a diffracted beam, termed a g_{hkl} reflection, down the optic axis of the microscope (in contrast to moving the aperture over the diffraction spot, which would increase aberrations and degrade resolution). Areas where the $\{hkl\}$ planes diffract strongly appear bright in such cases. Weak beam images can also be produced under dark field imaging conditions, with the sample tilted slightly away from a strong Bragg condition. The trade-off, in this instance, is reduced image contrast for improved resolution, which allows fine detailed features, such as partial dislocations bounding dissociated dislocations, to be delineated.

By way of example, Fig. 17.14 shows the different contrasts obtained from a plan-view $\text{Si}/\text{Si}_{0.96}\text{Ge}_{0.04}/\text{Si}(001)$ sample foil imaged under bright-field and weak-beam diffraction conditions, respectively. The sample foil contains orthogonal arrays

Fig. 17.14 (a) Bright-field and (b) weak-beam plan-view TEM images of $\text{Si}/\text{SiGe}/\text{Si}(001)$

of interfacial misfit dislocations that are generated as a consequence of the relaxation of the strain arising from the different lattice parameters of Si and $\text{Si}_{0.96}\text{Ge}_{0.04}$ [17.16]. The strain fields around the dislocations lead to a local deviation away from the exact Bragg condition, which can be used to delineate the (approximate) positions of the dislocation cores. The weak beam technique allows the complex dislocation tangle to be resolved more clearly. Imaging such sample foils using different diffraction vectors produces different contrasts that allow the nature of the dislocations to be precisely determined. Hence, the dislocation reaction mechanisms responsible for microstructure development can, in principle, be identified.

Some examples are now presented that illustrate how electron diffraction can contribute to the structural characterization of semiconductors. The use of conventional TED combined with image contrast analysis to assess the defect microstructure of a semiconductor heterostructure is initially considered. The application of the CBED technique, sometimes termed microdiffraction, in order to determine the polarities of noncentrosymmetric crystals is then described. We also focus on the RHEED technique, which may be used for rapidly assessing the near-surface microstructures of semiconductor thin films.

17.4.1 Electron Diffraction and Image Contrast Analysis

Figure 17.15 shows a TED pattern corresponding to a highly symmetric, low-index, zone axis projection, acquired from an electron-transparent foil of epitaxial GaN grown on the {0001} basal plane of sapphire, viewed in cross-section under spread beam conditions, in other words near-parallel illumination.

It is generally instructive to view such diffraction patterns alongside other images of the sample. Figure 17.16 compares high-resolution electron microscopy (HREM) and conventional TEM (CTEM) images of heteroepitaxial GaN–sapphire that were acquired for this projection. The HREM mode of imaging, otherwise termed ‘phase contrast’ or ‘lattice imaging’, makes use of several diffracted beams selected by a large objective aperture; the resulting interference patterns can be used to elucidate the locations of atomic columns (Fig. 17.16a). Careful simulation is required to precisely assign the atomic positions within such images, since the contrast is strongly dependent on defocus,

foil thickness and sample orientation. However, the structural integrity of the interface between GaN and sapphire can be appraised, along with the presence of nanometer-scale, three-dimensional growth islands formed during the initial stages of epitaxy, prior to layer coverage. Conversely, the conventional ‘many-beam, bright-field’ image of heteroepitaxial GaN–sapphire (Fig. 17.16b) was created using a small objective aperture placed over the directly transmitted beam, and recorded at lower magnification. The image contrast is again complicated because there are many excited diffracted beams operating for this low-index crystal orientation and strain fields associated with the large number of threading defects ($\approx 10^{10} \text{ cm}^{-2}$) within this sample. Despite this level of defect content, the diffraction pattern of Fig. 17.15 still reflects the high level of crystallographic perfection of the matrix. Also, rotation of this sample foil by 30° about the growth axis enabled a $\langle 1\bar{1}00 \rangle_{\text{nitride}} || \langle 11\bar{2}0 \rangle_{\text{sapphire}}$ projection to be established, consistent with the hexagonal symmetry of this GaN–sapphire system. Indeed, establishing different diffraction patterns for different sample projections, for known angles of sample tilt, enable the phase and structural relationship of an epilayer and substrate to be readily established.

There is a need to characterize the precise nature of the fine-scale defect content within such samples. Dislocations, for example, generally act as nonradiative recombination centers, which can deleteriously affect the charge transport properties of a semiconductor [17.17]. Gaining an improved understanding of how dislocations are created and how they interact enables us to identify mechanisms that could be used to control their development, thereby improving growth of semiconductor material and the resultant properties of devices made from it.

Dislocations are one-dimensional defects that can be pure edge, pure screw or ‘mixed edge-screw’ in character. In certain circumstances, dislocations can dissociate

Fig. 17.15 TED pattern acquired from epitaxial GaN/sapphire{0001} viewed in cross-section, corresponding to the $\langle 11\bar{2}0 \rangle_{\text{nitride}} || \langle 1\bar{1}00 \rangle_{\text{sapphire}}$ axis projection

Fig. 17.16 (a) HREM and (b) many-beam CTEM images of GaN/sapphire{0001}

to form a pair of partial dislocations bounding a stacking fault ribbon, the separation of which depends on the material stacking fault energy. Dislocations can be described with reference to their line direction \mathbf{u} and Burgers vector \mathbf{b} , representing the closure failure of a loop of equal atomic spacing around the defect core. Dislocations can move through a crystal lattice by glide or climb mechanisms; for example, when under deformation or as part of a strain relaxation mechanism during heteroepitaxial growth. Also, dislocations can interact to either self-annihilate or multiply to generate more dislocations depending on their respective type, habit plane and the slip system of the matrix.

The technique of diffraction contrast analysis allows the nature of dislocations to be ascertained. The approach used is to tilt the sample away from the highly symmetrical, low-index zone axis orientation in order to establish diffraction contrast images under selected “two-beam” conditions, with one strong diffraction spot excited (\mathbf{g}) in addition to the central transmitted beam, corresponding to one set of crystal planes at the Bragg condition. When $\mathbf{g} \cdot \mathbf{b} = 0$, the displacement associated with a dislocation does not affect the diffracting planes used to form the image and so the defect appears invisible. In practice, two examples of this invisibility condition are generally required to determine the precise displacement associated with a given defect. The dislocation will appear visible when $\mathbf{g} \cdot \mathbf{b} = 1$ and might show a more complex double image for the case of $\mathbf{g} \cdot \mathbf{b} \geq 2$. Since a screw dislocation is characterized by a Burgers vector \mathbf{b} parallel to the line direction \mathbf{u} , the defect is invisible if a diffraction vector perpendicular to the line direction is chosen. In the case of an edge or mixed dislocation where \mathbf{b} is not parallel to \mathbf{u} , there is the stricter requirement for both $\mathbf{g} \cdot \mathbf{b} = 0$ and $\mathbf{g} \cdot (\mathbf{b} \times \mathbf{u}) = 0$ for true invisibility, otherwise residual contrast might be present that acts to confuse the image interpretation. We should also mention the deviation parameter s when establishing a diffracting condition, which represents the distance in reciprocal space from the exact Bragg condition, since this is associated with imaging artefacts such as extinction contours and thickness fringes that may act to further complicate an image.

Bright-field, dark-field or weak-beam diffraction contrast imaging techniques can be used for defect analysis, depending on the resolution required. By way of example, epitaxial GaN-($\overline{1}\overline{1}\overline{1}$)B GaAs grown by molecular-beam epitaxy (MBE) at 700 °C exhibits a mosaic cell structure with subgrain boundaries delineated by predominantly mixed-type threading dislocations (typically $> 10^{11} \text{ cm}^{-2}$) [17.18]. The

Fig. 17.17a–c Weak-beam images of the same regions of a GaN epilayer viewed in cross-section using (a) $\mathbf{g} = 000\overline{2}$ and (b) $\mathbf{g} = 1\overline{1}00$. (c) Schematic diagram summarizing Ishida’s rule for determining \mathbf{b} for $n = -2$ and $n = 2$

epitaxial relationship is given by $[000\overline{1}]_{\text{GaN}} \parallel [\overline{1}\overline{1}\overline{1}]_{\text{GaAs}}$, $[1\overline{1}00]_{\text{GaN}} \parallel [2\overline{1}\overline{1}]_{\text{GaAs}}$ and $[11\overline{2}0]_{\text{GaN}} \parallel [01\overline{1}]_{\text{GaAs}}$, so the mismatch between GaN and GaAs is 38.2% between $\{1\overline{1}00\}_{\text{GaN}}$ and $\{2\overline{2}0\}_{\text{GaAs}}$, with the epilayer in tensile strain. Figures 17.17a,b are weak-beam images of the epilayer viewed in cross-section near the $[11\overline{2}0]$ zone axis, using $\mathbf{g} = 000\overline{2}$ and $\mathbf{g} = 1\overline{1}00$, respectively. Most of the dislocations have a line direction of $\langle 0001 \rangle$. Examples of perfect edge, $\mathbf{b} = 1/3\langle 11\overline{2}0 \rangle$, and screw-type dislocations, $\mathbf{b} = \langle 0001 \rangle$, are apparent, but mostly dislocations (typically $\approx 70\%$) can be seen in both images, hence they are mixed-type, with Burger’s vector components of \mathbf{a} and \mathbf{c} , in other words $1/3\langle 11\overline{2}3 \rangle$.

It is possible to move this analysis forwards by applying Ishida’s rule, which allows the magnitude and sense of a Burgers vector to be determined if there are terminating thickness fringes at the exit of a dislocation from a wedge-shaped sample foil [17.19]. If there are n fringes terminating at one end of a dislocation, then $\mathbf{g} \cdot \mathbf{b} = n$ and the sign of n ($n > 0$ or $n < 0$) is defined according to Fig. 17.16c. For example, the screw dislocation S (Fig. 17.17a) imaged using $\mathbf{g} = 000\overline{2}$ has two thickness fringes terminating on the right-hand side of the dislocation, with the dislocation line pointing towards the $[000\overline{1}]$ growth direction. Therefore $\mathbf{g} \cdot \mathbf{b} = -2L = 2$, so \mathbf{b} is $[000\overline{1}]$ for this screw-type dislocation. For dislocations of mixed type, Figs. 17.17a,b show that some have strong contrast in both images, while others have strong contrast when imaged using $\mathbf{g} = 000\overline{2}$ and weak contrast when $\mathbf{g} = 1\overline{1}00$. For the former, for example the dislocation pointed out as M_s in Fig. 17.17a, thickness fringes terminate at the left-hand side of the dislocation with reference to the dislocation line pointing downwards

along $[0001]$. Hence, $\mathbf{g} \cdot \mathbf{b} = -2L = -2$ for $\mathbf{g} = 000\bar{2}$ and $\mathbf{g} \cdot \mathbf{b} = -1$ for $\mathbf{g} = 1\bar{1}00$, so its Burgers vector is either $1/3[\bar{2}113]$ or $1/3[\bar{1}2\bar{1}3]$. For the cases of strong contrast by $\mathbf{g} = 000\bar{2}$ and weak contrast by $\mathbf{g} = 1\bar{1}00$, such as the dislocation labeled M_w in Fig. 17.17b, such dislocations have \mathbf{b} of $\pm 1/3[11\bar{2}3]$ or $\pm 1/3[11\bar{2}\bar{3}]$, and the weak contrast is due to $\mathbf{g} \cdot (\mathbf{b} \times \mathbf{u}) \neq 0$. Because the thickness fringes connected with this defect type are not clear in the images, a more precise value for \mathbf{b} cannot be determined. It is also noted that some dislocations have opposite values of \mathbf{b} to others, such as those marked as M and N in Fig. 17.17a. These two opposite types of dislocations delineate a subgrain. The region showing bright contrast when imaged with $\mathbf{g} = 1\bar{1}00$ in Fig. 17.17b is also a misoriented subgrain, tilted close to the Bragg condition.

17.4.2 Microdiffraction and Polarity

If the electron beam converges to form a focused probe at the sample, then there will be a range of beam directions within the incident probe and within the transmitted and diffracted beams. This leads to the formation of diffraction patterns comprising discs rather than spots. The fine detail within such microdiffraction or CBED patterns contains space and point group information. Such patterns also provide a sensitive measure of lattice pa-

rameters and strain within a sample, and can also be used to assess defect type.

Two examples showing how focused probe diffraction patterns may be used to determine the absolute polarities of sphalerite and wurtzite noncentrosymmetric crystals, in situ in the TEM, are now illustrated. It is often important to know the polar orientation of a heterostructure since this can strongly influence the mode and rate of growth, the incorporation of dopants or impurities, and the development of extended defects, and hence the functional performance of the resulting device structure. The opposite polar faces of noncentrosymmetric crystals [17.20] may be distinguished in practice using appropriate chemical etchants. However, such reagents are discriminatory in their action and need to be correlated with some other experimental technique for the purpose of absolute polarity determination. For most cases of diffraction, there is no difference between the intensities of beams scattered by the hkl and $\bar{h}\bar{k}\bar{l}$ reflection planes. This indeterminacy is known as Friedel's law. However, the technique of microdiffraction coupled with a breakdown in Friedel's law allows the absolute polarities of sphalerite crystals to be determined when the anion and cation sizes are very similar (as with GaAs, ZnSe and CdTe) [17.21]. The diffraction condition shown in Fig. 17.18a corresponds to a projection tilted $\approx 10^\circ$ off a GaAs $[110]$ zone axis, arrived at fol-

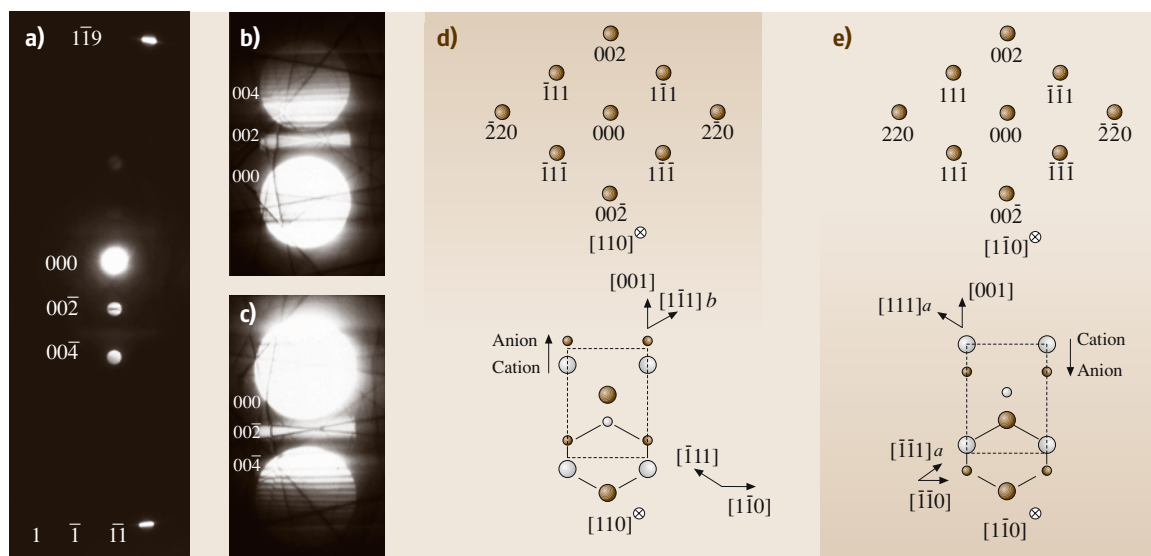

Fig. 17.18 (a)–(c) Microdiffraction patterns from $[110]$ GaAs. (d),(e) Sphalerite space lattice and reciprocal lattice projections for $[110]$ and $[1\bar{1}0]$, indexed for an electron beam traveling down into the page

lowing an $\sim 00\bar{4}$ Kikuchi band. The interaction of the doubly diffracted high-order, odd-index $1\bar{1}9$ and $1\bar{1}\bar{1}$ beams with directly scattered $00\bar{2}$ reflection gives rise to destructive interference through the $00\bar{2}$ disc when all of the reflections are close to the Bragg position. Figure 17.18c, corresponding to a more highly converged incident electron beam, emphasizes the formation of the dark cross through the $00\bar{2}$ diffraction disc. Similarly, Fig. 17.18b accentuates the bright cross through the opposite 002 diffraction disc, formed by constructive interference following interaction with the corresponding $1\bar{1}11$ and $1\bar{1}9$ high-order, odd-index reflections. Figures 17.18d,e, showing the $[110]$ and $[1\bar{1}0]$ projections of the sphalerite space lattice and reciprocal lattice, respectively, are also shown here, to aid understanding of this particular sample geometry. Establishing such microdiffraction patterns requires carefully balancing crystal orientation, probe convergence and layer thickness, and the technique is found to work best with freshly plasma-cleaned sample foils to minimize the effect of extraneous hydrocarbon contamination (which diffuses out the fine-scale contrast under the imaging electron beam).

The dynamical equations of electron diffraction demonstrate that the 002 reflection, which exhibits constructive interference effects (a bright cross), always occurs in the sense of the cation to anion to bond (Fig. 17.18d), and hence is always associated with the sense of advancing $\{\bar{1}\bar{1}\}_b$ planes. To emphasise this, defining $[001]$ as the growth direction of an epilayer on an (001) oriented GaAs substrate, and establishing a bright cross through an 002 diffraction disc, for example through the interaction of $1\bar{1}9$ and $1\bar{1}\bar{1}$ reflections, corresponds to the sense of advancing $(\bar{1}\bar{1})_b$ and $(1\bar{1})_b$ planes in the growth direction, which corresponds to the absolute $[110]$ projection of the sample foil. Conversely, a dark cross through an 002 diffraction disc, such as that obtained through the interaction of $1\bar{1}9$ and $1\bar{1}11$ reflections, corresponds to the sense of advancing $(111)_a$ and $(\bar{1}\bar{1}\bar{1})_a$ planes in the growth direction, which corresponds to the $[1\bar{1}0]$ projection of the sample foil. Since microdiffraction patterns are directly sensitive to crystallographic polarity, a qualitative interpretation of results thus allows the crystal orientation to be unambiguously determined, in situ within the TEM, without reference to any other technique.

Contrast reversals within diffraction discs of systematic row CBED patterns can similarly be used to determine absolute crystal polarity, since Friedel's law again breaks down due to dynamical scattering. In prac-

Fig. 17.19 Inversion domain within GaN with CBED patterns recorded across the boundary plane *inset*

tice, this approach is found to be most effective when used with noncentrosymmetric crystals that have much larger differences in anion and cation sizes, such as wurtzite GaN [17.22]. Figure 17.19 corresponds to a thin section through a columnar defect, imaged within homoepitaxial GaN grown on an N-polar $(000\bar{1})$ GaN substrate, with two associated CBED patterns inset, recorded either side of the boundary plane corresponding to matrix and core material, respectively. Simulation of the contrast within the 0002 diffraction discs, for a known sample foil thickness, demonstrates that the central bright and dark bands correspond to N and Ga-polar growth directions, respectively. The reversal of contrast within the 0002 diffraction discs across the boundary plane therefore indicates an inversion in crystal polarity, confirming the defect to be an inversion domain in this instance.

17.4.3 Reflection High-Energy Electron Diffraction

Electron-transparent samples are required for TED investigations. In the case of semiconductor heterostructures, for example, sample preparation requires sequential mechanical polishing and ion beam thinning, which can be very time-consuming, but the advantage of this approach is that diffraction data can be directly correlated with the projected image of the internal structure of the sample. A complementary approach is to use glancing angle electron diffraction techniques to characterize the near-surface microstructure of a bulk sample or an as-grown wafer. Coupling of the electron beam with the material surface at low angle allows scattering of the electrons to occur to produce a diffraction pat-

tern that may be viewed directly on a phosphor screen. This provides valuable information on the near-surface crystallography of the sample, which can be correlated with the growth conditions used or applied surface modifications, without the need for time-consuming sample preparation.

There are three variants of reflection electron diffraction (RED) depending on the accelerating voltage available: low (< 1 kV), medium (1–20 kV) or high (20–200 kV) energy. Medium-energy electron diffraction (MEED) systems are commonly associated with UHV growth chambers, whilst a variant of RHEED can be performed using a conventional TEM. In general terms, coupling of an electron beam with a flat single crystal tends to be associated with the formation of diffraction streaks normal to the surface, providing information on the reconstruction of the atomic layer at the surface. More precisely, streaky RED patterns are indicative of a surface that is not quite perfectly flat, but has slight local misorientations combined with some degree of surface disorder [17.23]. When electrons are coupled with a slightly rougher surface, there is a tendency for more three-dimensional information to be obtained from the interaction with the near-surface microstructure. This leads to the production of spotty diffraction patterns from crystalline materials (half-obscured by the sample shadow edge), in an analogous fashion to TED. It is noted that UHV-MEED systems also allow the intensity fluctuations within the central beam to be monitored in real time, and this provides a way to control layer-by-layer growth.

In practice, RHEED is most effectively used for rapid comparative studies of sets of samples; for example for appraising the effect of changing the growth parameter on the structural integrity of a deposited thin film [17.24]. This approach to process mapping provides a convenient way to identify appropriate samples for more detailed TEM investigation prior to sample foil preparation. There are two variants of the RHEED technique that may be used in a TEM: one where small samples are mounted vertically in the objective lens pole piece, and the other where larger samples are mounted vertically below the projector lens; we focus on the latter variant here.

A schematic diagram of the diffraction geometry for a RHEED experiment is shown in Fig. 17.20a. The diffraction spacing R_{hkl} can be measured and the associated crystal plane spacing d_{hkl} determined using the equation, $\lambda L = R_{hkl} d_{hkl}$, where λL is known as the camera constant. Figures 17.20b,c show a RHEED stage made to interface with a TEM through an existing camera port at the base of the projector lens. The vacuum system of the TEM vents the space below the projector lens upon opening the camera chamber, and so the only waiting time is for the chamber to pump down upon changing a specimen. The RHEED stage is able to support centimeter-square sections of a crystalline specimen, whilst full tilt, twist and lateral movement enables any zone axis within the growth plane of the sample to be accessed. A shadow image of a sample, as projected onto the microscope phosphor screen, is shown in Fig. 17.20d. The area sampled by the glancing elec-

Fig. 17.20 (a) Schematic diagram of the RHEED diffraction geometry; (b) RHEED stage; (c) magnified view of the sample holder; and (d) projected shadow image of a specimen on the microscope phosphor screen

tron beam is typically $\approx 1 \text{ mm}^2$, and so this experimental arrangement is closely associated with XRD, although the acquisition time for RHEED data is extremely short, with photographic plate exposure times of $\approx 1 \text{ s}$. Three or four samples can typically be examined within an hour.

The 100 kV RHEED patterns shown in Figs. 17.21a,b were acquired from a highly Si-doped GaN/GaAs(001) heterostructure, grown by MBE at 700°C , before and after plasma cleaning. Surface hydrocarbon deposits arising from specimen handling can generate an amorphous background glow that can hinder RHEED pattern

acquisition (Fig. 17.21a). The oxygen–argon plasma acts to remove such contaminants, allowing high-contrast RHEED patterns to be obtained (Fig. 17.21b). In this instance, the generated RHEED pattern remained effectively constant as the sample was rotated, indicating a random distribution of columnar grains. This predicted microstructure was subsequently confirmed by means of conventional plan-view TEM imaging (Fig. 17.21c, with TED pattern inset), which revealed a fine-scale distribution of rotated columnar grains ($\approx 20^\circ$ of arc).

The RHEED patterns shown in Figs. 17.22a–f, acquired from a variety of III–V heterostructures grown by MBE, are presented to illustrate the variety of microstructures that can be readily distinguished. In the first instance, variations in spot, arc or ring spacings from the central beam provide evidence of the different phases present within a sample and show the general nature of the structural integrity of the near-surface layer (presumed to be representative of the bulk or thin film). Thus, polycrystalline, preferred orientation or single-crystal growth (Fig. 17.22a–c) can be rapidly distinguished, whilst embedded phases (Fig. 17.22d) and anisotropic defect distributions within zinc blende thin films (Fig. 17.22e,f) are also revealed.

Fig. 17.22a–f RHEED patterns from (a) GaAs/AlN(As)/GaP(001) indicating polycrystalline growth; (b) GaN(As)/GaP(001) grown under low As flux at 620°C showing disordered growth with some degree of preferred orientation; (c) Mg-doped GaN/GaAs{111}B showing α -GaN single-crystal ($\langle 11\bar{2}0 \rangle$ projection); (d) GaN(As)/GaP(001) grown under high As flux at 650°C showing spots due to single-crystal GaAs and β -GaN; (e), (f) Be-doped GaN/GaAs(001) grown at 700°C showing orthogonal $\langle 110 \rangle$ and $\langle 1\bar{1}0 \rangle$ projections. Extra spots indicate a high degree of anisotropy for the distribution of defects within this sample

17.5 Characterizing Functional Activity

There are many solid state analytical techniques that employ X-ray or electron probes, generating a variety of signals for chemical microanalysis. Techniques for performing correlated assessment of the structural and functional performance of a material are perhaps less well-covered in mainstream texts. Accordingly, we now briefly introduce the techniques of scanning transmission electron beam induced conductivity (STEBIC) and TEM-cathodoluminescence (TEM-CL), since these allow us to make correlated structure–property investigations of electrical and optical activity within a semiconductor, respectively.

As discussed earlier, when an electron beam is incident on a semiconductor specimen, electron–hole pairs are created by the excitation of crystal electrons across the band-gap. These electron–hole pairs can, for example, recombine to emit light that may be detected by a photomultiplier. A CL image can then be obtained by displaying the detected photomultiplier signal as a function of the position of the incident electron beam as it is scanned across the specimen. CL spectra can also be acquired in spot mode, which show features attributable to excitons, donor–acceptor pairs or impurities. The ‘information content’ of CL images and spectra therefore includes the location of recombination sites such as dislocations and precipitates, and the presence of doping-level inhomogeneities. Similarly, if the sample is configured to incorporate a collection junction, such as a Schottky-contacted semiconductor or an ohmic-contacted p–n junction, electron–hole pairs that sweep across the built-in electric field constitute current flow. This can be amplified and an image of the recombination activity displayed as the electron beam is rastered

across the sample. If the dislocations within a semiconductor act as nonradiative recombination centers, then they appear as dark lines in both CL and EBIC images because of the reduced specimen luminescence or reduced current that is able to flow through the collection junction when the beam is incident at a defect.

The techniques of CL and EBIC are most commonly performed in an SEM, but this precludes the direct identification of features responsible for a given optical or electronic signature. The resolution of extended defects achieved using EBIC and CL techniques is limited by the penetration depth of the electron beam, the effect of beam spreading and the diffusion length of minority carriers. Conversely, the resolutions of the STEBIC and TEM-CL techniques, as applied to an electron-transparent sample foil, are essentially limited by specimen geometry. The constraint of minority carrier diffusion length is removed due to the close proximity of the sample foil surfaces, and resolution depends on the incident probe size, the width of the electron hole pair generation zone and the recombination velocity at the free surface. For the case of STEBIC, resolution also depends on the defect position relative to the collecting junction. The trade-off is low electrical signal and a degraded signal-to-noise ratio due to the small generation volume and surface recombination effects, in addition to the practicality of contacting and handling thin foils.

Before presenting a number of material characterization case studies based on electron beam techniques, we now discuss the preparation of electron transparent foils that are free from artefacts and suitable for TEM investigation.

17.6 Sample Preparation

We should initially consider whether destructive or non-destructive preparative techniques need to be applied. Some characterization techniques allow samples to be examined with a minimal amount of preparation, provided they are of a form and size that will fit within the apparatus. For example, the crystallography of bulk or powder samples could be directly investigated by XRD, since the penetration depth of energetic X-rays within a sample is on the scale of $\approx 100\ \mu\text{m}$. The surface morphology and near-surface bulk chemistry of a sample can be directly investigated within the SEM, noting the inter-

action volume of electrons [on the scale of $\approx 1\ (\mu\text{m})^3$] associated with the EDX and WDX techniques. It might, however, be necessary to coat insulating samples with a thin layer of carbon or gold prior to SEM investigation to avoid charging effects. Similarly, minimal preparation might only be required before surface assessment using XPS or RHEED, such as cleaning using a degreasing protocol or plasma cleaning. Accordingly, the focus of this section is to introduce the techniques used to prepare samples for TEM investigation, since the requirement is for specimens that are typically submicrometer in

thickness and free of preparation artefacts. For example, a complex sequence of sequential mechanical polishing, dimpling, ion beam thinning and plasma cleaning may be required to produce a pristine semiconductor heterostructure sample, with each stage of the process being designed to minimize artefacts from the previous stage of the preparation process. The idea is to minimize or eliminate artefacts from the preparation process to ensure that the sample being investigated is representative of the starting bulk material. Care is also needed to avoid artefacts that might be introduced through the interaction of the high-energy electron beam with the sample.

In this context, it is interesting to note how TEM sample preparation techniques have developed over the years. Small particles of MgO, produced by igniting the metal and drifting a specimen grid through the smoke, were typical of samples investigated in the 1940s, along with sample replicas made by a dry stripping technique using formvar film. Biological samples fashioned by enzymatic digestion, staining and microincineration were also possible by 1945. Glass and diamond knife microtomes were introduced in the 1950s and used to section soft biological materials. Advances in the controlled preparation of inorganic materials were made upon the introduction of argon ion beam thinning in the late 1960s, which allowed the cross-sectional observation of semiconductor heterostructures when combined with sequential mechanical polishing and dimpling. Significant development work in this area appears throughout the literature from the 1970s. The problem of surface amorphization, introduced by the argon sputtering process, was minimized by adopting low-voltage milling techniques to define the final electron-transparent sample foil. Low stacking fault energy semiconductors, such as II–VI compounds which are easily damaged or InP-based compounds that suffer from In droplet formation with conventional milling techniques, were also successfully prepared for TEM observation using the technique of iodine reactive ion beam etching (RIBE), otherwise known as chemically assisted ion beam etching (CAIBE), developed in the 1980s. The 1990s, however, saw the development of the most effective raft of sample preparation techniques for functional materials and complex semiconductor device structures in particular: tripod polishing, focused ion beam (FIB) milling and plasma cleaning.

The fine adjustment of micrometer supports is the key to tripod polishing that allows the direct mechanical polishing of specimens down to thickness of $< 10\ \mu\text{m}$, using diamond-impregnated polishing cloths on a stable,

high-torque, low-speed polishing wheel. A brief final stage of low-voltage argon ion beam thinning (with liquid nitrogen cooling) then enables electron-transparent sample foils to be defined, free of differential mechanical polishing and shadowing artefacts, whilst minimizing remnant surface amorphization.

FIB instrumentation (now commonly integrated with an SEM) was originally developed for the semiconductor industry as a diagnostic tool for silicon chip fabrication. The application of a focused beam of gallium ions enables sample material to be sputtered away in a controlled fashion to produce an electron-transparent membrane, for example through a specific device within a complex microprocessor. Samples can be periodically observed using SEs generated by gallium ion/material interactions in order to maintain control over and the precision of the sputtering process. In particular, the ability of FIB instruments to prepare site-specific TEM membranes provides a unique opportunity to access the subsurface microstructure of complex device structures

Fig. 17.23a–d SE images showing the application of FIB milling to target a source of defects buried beneath the emergent core of a growth hillock. **(a)** An etched CVD-grown GaN/sapphire hillock ($\approx 5\ \mu\text{m}$ in size). **(b)** Platinum stripes deposited along the hillock facet edges in order to retain sight of the defect core ($\approx 100\ \text{nm}$ in size). **(c)** A high Ga flux is used to create an access trench to the defect. **(d)** Decreasing the Ga flux enables an electron-transparent membrane (arrowed) to be defined at the approximate position of the defect core

Fig. 17.24a,b EELS spectra from GaN (a) before and (b) after plasma cleaning

or specific regions within a heterostructure identified as being particularly interesting from observations of the surface. Again, by way of example, Fig. 17.23 shows a TEM membrane sectioned through the apex of a hillock identified within a sample of heteroepitaxial GaN–sapphire. Prior to sectioning, the sample was coated with a thin layer of gold and a platinum alkyl decomposed under the rastered Ga beam to de-

fine protective metallic stripes. Sequential sputtering and reduction of the incident Ga beam current allowed a supported thin membrane to be defined (Fig. 17.23d). Care is still required to minimize amorphization artefacts at the surfaces of such membranes, arising from the sputtering action of the glancing, high-energy Ga ion beam. Charging effects associated with insulating samples can act to compromise the fine-scale control of the ion milling procedure. However, this particular problem can be addressed by using low ion dose and shadowing techniques, combined with charge neutralization procedures to inhibit the deflection of the incident ion beam.

Plasma cleaning using oxygen–argon gas, commonly used for the final stage of TEM sample preparation, enables pristine electron-transparent membranes to be obtained, suitable for detailed chemical microanalysis. The disassociated oxygen component of the plasma reacts with organic surface contaminants to produce CO, CO₂ and H₂O reaction products that can be conveniently pumped away. To illustrate the effectiveness of this procedure, it was found that the quality of EELS data from GaN was significantly improved following plasma cleaning. Figure 17.24 shows the removal of the artefact carbon K-edge and enhancement of the sample nitrogen K-edge after a few minutes of exposure to the plasma. It is worth noting that in principle the argon component of the plasma permits gentle sputtering of the sample to occur if low-pressure conditions are used due to the larger mean free path and hence increased energy of the ions. This can be problematic due to the possibility of sample cross-contamination with material sputtered from the supporting sample rod. Another cautionary note on plasma cleaning relates to semi-insulating samples that can become too clean and consequently more susceptible to charging effects under the imaging electron beam.

17.7 Case Studies – Complementary Characterization of Electronic and Optoelectronic Materials

There are four general levels of interest when characterizing a given sample:

- What is it made of?
- What additional imperfections does it contain?
- How did it get to be that way?
- How does the microstructure influence the functional properties of the material/device?

For example, one might wish to identify the chemical constituents and crystal structure of a sample to start with, such as whether it is a compound or an alloy, and whether it is single-crystal, polycrystalline, exhibits a preferred orientation or is amorphous. One might then wish to characterize the additional fine-scale defect microstructure within the sample, including precipitates or extended structural defects such as dis-

locations, stacking faults or domain boundaries, since these could deleteriously affect the functional properties of the material. The next level of understanding focuses on how the material has formed via growth, processing or device usage, and seeks to make sense of the process of dynamic evolution, since this potentially enables us to find ways to improve the material in a controlled manner. A clear record of sample history is generally helpful in this context, particularly when trying to identify defect sources. The final level of understanding is possibly the most challenging, since it seeks to associate microstructure with the functional properties exhibited by the sample, and thereby to make sense of its structure–property–processing interrelationship at the fundamental level.

In this context, structural characterizations of semiconductor heterostructures tend to focus on the following issues:

- The integrity of the layer growth and the orientation relationship with the substrate.

- The nature of the structural defects within the epilayer, arising (for example) from the lattice mismatch or from differential thermal contraction following cool-down from the growth temperature.
- The structural integrities of the critical interfaces within the device's active region, such as multiple quantum wells, and the chemical uniformities of the associated alloy layers.
- Modification of the microstructure due to subsequent processing, such as contact formation and device usage.

XRD techniques are well-suited to assessments of the structural integrities of bulk and epitaxial thin film semiconductors. However, we should note the inherent averaging over a large number of microscopic features, such as dislocation distributions responsible for twist and tilt of mosaic grains, associated with such techniques. Conversely, TEM and related techniques are more suited to assessing the fine-scale defect microstructure of a heterostructure. For example, conventional

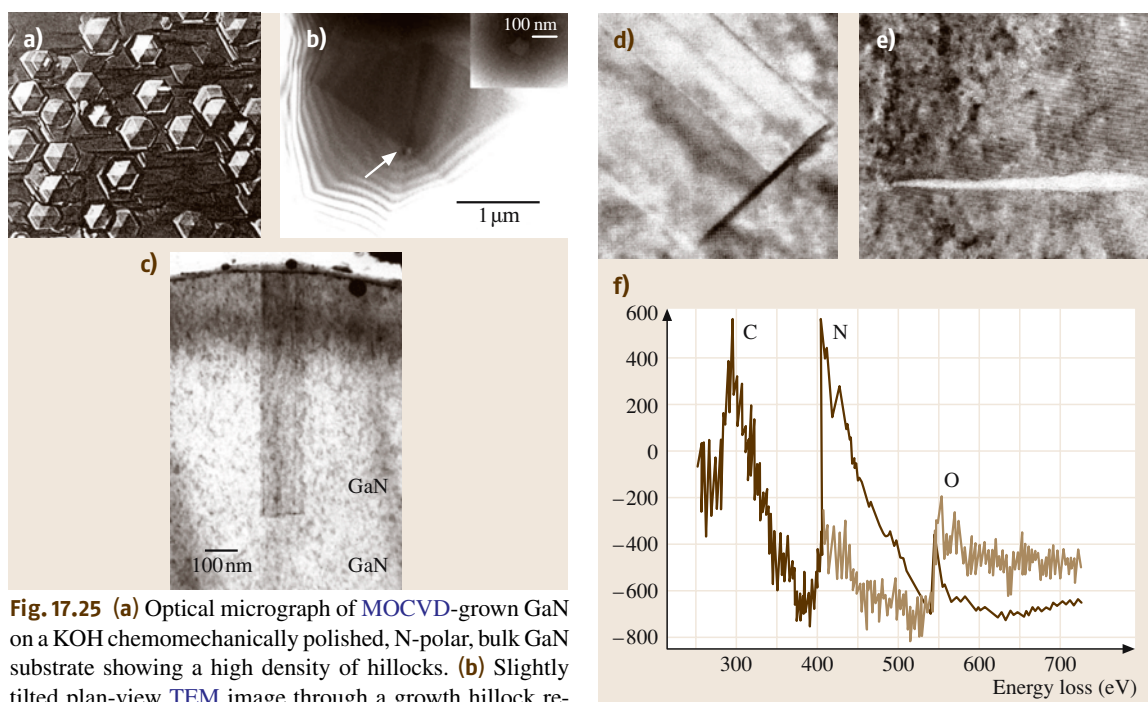

Fig. 17.25 (a) Optical micrograph of MOCVD-grown GaN on a KOH chemomechanically polished, N-polar, bulk GaN substrate showing a high density of hillocks. (b) Slightly tilted plan-view TEM image through a growth hillock revealing a central defect core (arrowed). An enlarged $\langle 0001 \rangle$ projected image of the hillock core is shown in the inset. (c) Cross-sectional, weak-beam TEM image through a hillock core. CBED analysis confirmed the feature to be an inversion domain. (d) HAADF image indicating the

presence of a low atomic number material at the inversion domain source. (e) HREM image indicating the presence of a narrow band of amorphous material at the inversion domain source. (f) EEL second difference spectrum indicating the presence of oxygen at the nucleating event

weak-beam, HREM or CBED analysis can be used for fine-scale defect structural analysis, whilst EELS and EDX analysis can be used to profile alloy composition. However, the ability to perform atomic-level structural characterization and chemical analysis on the nanometer scale is offset by concerns about statistical significance and whether the small volume of material analyzed is truly representative of the larger object. Therefore, electron microscopy-based techniques combined with FIB procedures for site-specific sample preparation tend to be used when investigating integrated device structures.

The examples provided so far illustrate how various diffraction and imaging techniques can provide information on the structural integrity of a given sample. The following examples emphasize the need to apply complementary material characterization techniques in support of the development of semiconductor science and technology.

17.7.1 Identifying Defect Sources Within Homoepitaxial GaN

The emergence of the (In,Ga,Al)N system for short-wavelength light-emitting diodes, laser diodes and high-power field effect transistors has been the semiconductor success story of recent years. In parallel with the rapid commercialization of this technology, nitride-based semiconductors continue to provide fascinating problems to be solved for future technological development. In this context, a study of homoepitaxial GaN, at one time of potential interest for high-power blue-uv lasers, is presented.

The reduction in extended microstructural defects permitted by homoepitaxial growth is considered to be beneficial in the development of nitride-based technology, particularly in view of the evidence confirming that dislocations do indeed exhibit nonradiative recombinative properties. However, in the case of metalorganic chemical vapor deposition (MOCVD)-grown homoepitaxial GaN on chemomechanically polished (000 $\bar{1}$), N-polar substrates, gross hexagonally shaped surface hillocks were found to develop, considered problematic for subsequent device processing [17.25]. The homoepitaxial GaN samples examined in this case study were grown at 1050 °C. The bulk GaN substrate material was grown under a high hydrostatic pressure of nitrogen (15–20 kbar) from liquid Ga at 1600 °C. Prior to growth, the (000 $\bar{1}$) surfaces were mechanically polished using 0.1 μm diamond paste and then chemomechanically polished in an aqueous KOH solution. Epitaxial growth was performed using trimethylgallium and NH_3 precursors

with H_2 as the carrier gas, under a total pressure of 50 mbar. Figure 17.25a shows an optical micrograph of the resultant homoepitaxial GaN/GaN(000 $\bar{1}$) growth hillocks, typically 5–50 μm in size depending on the layer thickness (and therefore the time of growth).

Electron-transparent samples were prepared in plan view using conventional sequential mechanical polishing and argon ion beam thinning procedures applied from the substrate side, whilst cross-sectional samples were prepared using a Ga-source FIB workstation. As shown earlier, the selectivity of the FIB technique enables cross-sections through the emergent cores of the hillocks to be obtained, thereby allowing the nucleation events associated with these features to be isolated and characterized. When prepared in plan-view geometry for TEM observation, each hillock exhibited a small faceted core structure at the center (Fig. 17.25b), but otherwise the layers were generally found to be defect-free. Low-magnification cross-sectional TEM imaging also revealed the presence of faceted column-shaped defects beneath the apices of these growth hillocks (Fig. 17.25c). It was presumed that these features originated at the original epilayer–substrate interface since no other contrast delineating the region of this homoepitaxial interface could be discerned. A reversal of contrast within the 0002 diffraction discs from CBED patterns acquired across the boundary walls of such features (Fig. 17.19) confirmed that they were inversion domains. Thus, the defect cores were identified as having Ga-polar growth surfaces embedded within an N-polar GaN matrix. Once nucleated, the inversion domains exhibited a much higher growth rate than the surrounding matrix, being directly responsible for the development of the “circus tent” hillock structures around them. Competition between the growth and desorption rates of Ga and N-polar surfaces allowed the gross hexagonal pyramids to evolve.

This initial approach of applying electron diffraction and imaging techniques thus enabled the nature of the inversion domains to be identified and their propagation mechanism established in order to explain the development of the hillocks. However, more detailed chemical analysis was required to ascertain the nature of the source of the inversion domains and how this related to the substrate preparation and growth process. A high-angle annular dark field (HAADF) image of the inversion domain nucleation event is shown in Fig. 17.25d. HAADF is a scanned electron probe imaging technique with a resolution defined by the size of the incident probe, while the scattering (and hence con-

trast) is governed by the local average atomic number. In this instance, the sample, tilted slightly to minimize the effects of diffraction contrast, showed dark contrast at the position of the inversion domain source, confirming the presence of a low atomic number material associated with the nucleation event. HREM subsequently confirmed that such nucleation events were due to narrow bands of amorphous material, 2–5 nm in thickness (Fig. 17.25e), whilst EELS confirmed the presence of oxygen (Fig. 17.25f) within these narrow amorphous bands. Accordingly, these defect sources were attributed to remnant contamination from the chemomechanical polishing technique used to prepare the substrates prior to growth. The oxygen-containing residue was presumed to be gallium oxide or hydroxide – probably products of the reaction of KOH etchant with GaN. An improved surface preparation method incorporating a short, final deoxidizing polishing procedure in an aqueous solution of NaCl led to a dramatic reduction in these nucleation sources and thus allowed N-polar homoepitaxial GaN films to be grown virtually free of these gross hillock structures.

17.7.2 Cathodoluminescence/Correlated TEM Investigation of Epitaxial GaN

The CL technique is ideally suited to studies of luminescence uniformity and spectral purity. The following case study illustrates how the defect microstructure of mixed-phase epitaxial GaN/GaAs(111)B can be correlated with the luminescent properties of the layer [17.26].

Even though the majority of developments in GaN technology to date have come from material grown by MOCVD on sapphire and SiC substrates, there is much interest in exploring alternative growth techniques. The MBE technique offers a lower growth temperature than MOCVD and hence enables a greater range of candidate substrate materials to be investigated. One general issue for the MBE growth of heteroepitaxial GaN is the need for direct control of the process of nucleation, since this impacts on the phase and polarity of the deposit and the resultant structural integrity of the film. Epitaxial GaN preferentially adopts the wurtzite phase, with a band-gap of 3.4 eV_{hex}, although zinc blende inclusions, with a band-gap of 3.2 eV_{cubic}, are sometimes associated with MBE-grown material (for conditions of high Ga flux); see Fig. 17.26. The CL spectrum shown in Fig. 17.26a was recorded from a plan-view, electron-transparent foil of nominally single-crystal wurtzite GaN, cooled to liquid nitrogen temperatures. The peak in the CL spectrum at 386 nm (3.21 eV) was used to cre-

Fig. 17.26 (a) CL spectrum acquired from an electron-transparent foil showing peaks at 357.8 nm and 386 nm, corresponding to wurtzite and zinc blende GaN, respectively; (b) CL image formed at 386 nm and (c) complementary TEM image confirming a distribution of cubic GaN inclusions (arrowed) embedded within the hexagonal GaN matrix; (d) HREM image of epitaxial GaN/GaAs(111)B viewed in cross-section, indicating the nucleation of cubic phase inclusions at the epilayer–substrate interface

ate the image in Fig. 17.26b indicating the distribution of cubic phase inclusions throughout the hexagonal GaN matrix. The complementary conventional TEM image of this plan-view sample foil (Fig. 17.26c) allows the nature of the fine-scale microstructure to be characterized, with diffraction patterns confirming the presence of embedded sphalerite GaN. The size and distribution of these inclusions correlated nicely with the distribution of bright spots in the CL image of 17.26b. A subsequent cross-sectional investigation of GaN/GaAs(111)B specimens confirmed that the cubic inclusions were nucleated at the epilayer/substrate interface (Fig. 17.26d).

Fig. 17.27 (a) Schematic of the Al/Si/Si_{1-x}Ge_x/Si(001)/InGa sample configuration used for STEBIC investigation.

17.7.3 Scanning Transmission Electron Beam Induced Conductivity of Si/Si_{1-x}Ge_x/Si(001)

The STEBIC technique was originally demonstrated in the late 1970s, using dedicated STEM instrumentation to obtain information on the electrical properties of dislocation core structures within (Ga,Al)(As,P), and thereby providing the first evidence that non-radiative recombination processes at dislocations are related to jogs and kink sites. Dissociated 60° dislocations showed the highest electrical activity, while sessile Lomer-Cottrell edge dislocations were found to be electrically neutral, indicative of reconstructed core structures. STEBIC imaging of an electron-transparent foil allows the electrical and structural properties of defects to be observed simultaneously. The availability of electron sources with high brightness in modern scanning TEM instruments compensates for the main problem of small generation volume and provides an accessible way to perform the STEBIC technique.

The next case study illustrates how the electrical nonradiative recombination properties of MBE-grown Si/Si_{1-x}Ge_x/Si(001) heterostructures correlate with the distribution of interfacial misfit dislocations [17.27]. The Si_{1-x}Ge_x system has potential applications in devices with high electron and hole mobilities. However, the introduction of dislocation networks, or the multiplication of existing dislocations, driven by the 4% misfit strain between Ge and Si, is generally regarded as being detrimental to device operation. With a view to gaining an improved understanding of the relationship between fine-scale structural defects and electron transport properties, structures of capped MBE-grown Si/Si_{1-x}Ge_x/Si(001) were investigated using STEBIC and a range of complementary microscopies. The samples incorporated buried p-n junctions to assist with charge collection and surmount the problem of surface recombination effects.

To prepare for the STEBIC investigation of the Si/Si_{1-x}Ge_x/Si(001), evaporated Al contacts were attached to the top surface prior to preparing electron-transparent foils in plan view by sequential mechanical polishing and argon ion milling of the substrate (Fig. 17.27a). Ohmic contact to the lower surface was made using an InGa eutectic. Electrical activity images were acquired using an electrical contact stage and a scanning TEM. Signal amplification was performed using an amplifier with a low noise current. By controlling the STEM scan rate, the beam could be rastered at a rate compatible with the low bandwidth constraint of the amplifier. STEBIC signals were typically ≈ 100 pA for an electron-transparent Si/Si_{1-x}Ge_x/Si foil imaged at a magnification of $\times 1000$.

Figure 17.27a illustrates the physical parameters relevant to this STEBIC experiment. The silicon substrate was n-type 10^{18} cm^{-3} , whilst the epilayer was p-type boron-doped to a level of 10^{16} cm^{-3} . These

Fig. 17.27 (b) STEBIC image showing recombination activity due to $\langle 110 \rangle$ orthogonal arrays of misfit dislocations within relaxed Si/Si_{0.96}Ge_{0.04}/Si(001). **(c)** Higher magnification STEBIC image illustrating sub- μm resolution of the electrical activity. **(d)** Bright-field TEM image demonstrating the presence of bundles of misfit dislocations ($g = 220$)

values of sample doping were chosen to create a depletion region of ≈ 30 nm width to assist with charge collection, away from the misfit dislocations delineating the $\text{Si}/\text{Si}_{1-x}\text{Ge}_x$ and $\text{Si}_{1-x}\text{Ge}_x/\text{Si}$ interfaces. The low-magnification STEBIC image shown in Fig. 17.27b illustrates the recombination activity within a relaxed $\text{Si}/\text{Si}_{0.96}\text{Ge}_{0.04}/\text{Si}(001)$ sample imaged in plan view. Submicron resolution of the recombination activity is readily achievable using this technique (Fig. 17.27c), with line scans from digitized images indicating a resolution of ≈ 0.3 μm in this case. The spacing of ≈ 1 μm striations in the STEBIC image is much greater than the spacing of individual misfit dislocations shown in the associated TEM image (Fig. 17.27d), and is more closely associated with the spacing of dislocation bundles. Thus, correlation with structural images shows that bunched arrays of orthogonal $\langle 110 \rangle$ misfit dislocations are primarily responsible for the enhanced recombination. For this particular sample, detailed *g.b* analysis confirmed the presence of bands of predominantly 60° misfit dislocations with a few 90° segments arising from dislocation interactions.

Supporting evidence for these dislocations being dissociated and probably decorated by transition metal impurities was obtained from complementary HREM and EDX investigations of metastable and relaxed $\text{Si}/\text{Si}_{1-x}\text{Ge}_x/\text{Si}(001)$ samples from the same growth trial. As the relaxation of a low Ge content, metastable $\text{Si}/\text{Si}_{1-x}\text{Ge}_x/\text{Si}$ structure proceeds, extensive arrays of orthogonal $\langle 110 \rangle$ dislocations form and interact, with dislocations generated in the strained $\text{Si}_{1-x}\text{Ge}_x$ layer being pushed by repulsive dislocation forces into the Si substrate and cap on $\{111\}$ glide planes. HREM observations of relaxed $\text{Si}/\text{Si}_{1-x}\text{Ge}_x/\text{Si}$ samples in cross-section confirmed that the misfit dislocations were dissociated, with tails associated with each of the partials, indicative of impurity decoration (Fig. 17.27e). This particular image was acquired before the development of electron beam-induced damage artefact structures within this sample foil and so is considered representative of the as-grown material. A distribution of small precipitates, of typical size 5 nm, was also identified within metastable samples prior to strain relaxation. These precipitates showed strong scattering in HREM (Fig. 17.27f) and revealed the presence of Fe when analyzed using EDX within a dedicated STEM (1 nm probe size), as shown in Fig. 17.27g. No Fe was present in spectra acquired immediately to the side of the precipitates. (The Ni signal was considered to be an artefact of EDX acquisition and attributed to fluorescence from X-rays and electrons interacting with the specimen's Ni

Fig. 17.27 (e) HREM image of a decorated dissociated dislocation viewed in cross-section at the $\text{Si}/\text{Si}_{1-x}\text{Ge}_x$ interface following sample annealing and relaxation. (f) HREM image of a precipitate within as-grown, metastable $\text{Si}/\text{Si}_{1-x}\text{Ge}_x/\text{Si}$.

Fig. 17.27 (g) EDX spectra confirming the presence of Fe transition metal impurities

support ring.) Hence, the suggestion is that enhanced transition metal impurity segregation at dissociated dislocations is responsible for the STEBIC contrast observed. This emphasizes the need to control dopants or impurity sources in the vicinity of the heterostructure interface during the development of functional device structures.

17.8 Concluding Remarks

The above commentary has attempted to convey the framework underpinning a variety of analytical techniques used to investigate the structures of semiconductors. It is emphasized that an appropriate combination of assessment techniques should generally be applied, since no single technique of assessment will provide information on the composition, morphology, microstructure and (opto)electronic properties of a given functional material or processed device structure.

This type of considered approach to materials characterization is required in order to break free of the “black-box” mentality that can develop if one is too trusting of the output generated by automated or computerized instrumentation systems. We must always bear in mind the process of signal generation that provides the information content. This in turn should help us to develop an appreciation of performance parameters such as spatial or spectral resolution, in addition to sensitivity, precision and the detection limit. We should consider technique calibration and the appropriate use of standards in order to ensure that the data acquired is appropriate (and reproducible) to the problem being addressed. Consideration should also be given to the form and structure of the data being acquired and how the data sets are analyzed. In this context, distinction should

be made between the processing of analog and digital information and the consequences of data conversion. Issues regarding the interpretation (or misinterpretation) of results often stem from the handling of experimental errors. On a practical level, a rigorous experimental technique should certainly be applied to ensure that the data generated is both meaningful and representative of the sample being investigated, free from artefacts from the preparation and investigation processes. There are clearly differences between qualitative assessment and the more rigorous demands of quantitative analysis. The level of effort invested often reflects the nature of the problem that is being addressed. A comparative assessment of a number of samples may simply require a qualitative investigation (for example, in order to solve a specific materials science problem within a growth or device fabrication process). Alternatively, quantitative analysis may be required to gain a more complete understanding of the nature of a given sample, such as the precise composition. To summarize, an awareness of the methodology used in any investigation is required to establish confidence in the relevance of the results obtained. A range of complementary analysis techniques should ideally be applied to gain a more considered view of a given sample structure.

Surface Chem

18. Surface Chemical Analysis

The physical bases of surface chemical analysis techniques are described in the context of semiconductor analysis. Particular emphasis is placed on the **SIMS** (secondary ion mass spectrometry) technique, as this is one of the more useful tools for routine semiconductor characterization. The practical application of these methods is addressed in preference to describing the frontiers of current research.

18.1 Electron Spectroscopy	373
18.1.1 Auger Electron Spectroscopy	373
18.1.2 X-Ray Photoelectron Spectroscopy (XPS)	375
18.2 Glow-Discharge Spectroscopies (GDOES and GDMS)	376
18.3 Secondary Ion Mass Spectrometry (SIMS)	377
18.4 Conclusion	384

Surface chemical analysis is a term that is applied to a range of analytical techniques that are used to determine the elements and molecules present in the outer layers of solid samples. In most cases, these techniques can also be used to probe the depth distributions of species below the outermost surface. In 1992 the International Standards Organisation (ISO) established a technical committee on surface chemical analysis (ISO TC 201) to harmonize methods and procedures in surface chemical analysis. ISO TC 201 has a number of subcommittees that deal with different surface chemical analytical techniques and this chapter will discuss the applications of these different methods, defined by ISO TC 201, in the context of semiconductor analyses. In particular, this discussion is intended to deal with practical issues concerning the application of surface chemical analysis to routine measurement rather than to the frontiers of current research. Standards relating to surface chemical analysis developed by the ISO TC201 committee can be found on the ISO TC201 web site www.iso.org (under “standards development”).

Traditional surface chemical analysis techniques include the electron spectroscopy-based methods Auger electron spectroscopy (**AES** or simply Auger) and X-ray photoelectron spectroscopy (**XPS**, once also known as ESCA – electron spectroscopy for chemical analysis), and the mass spectrometry method **SIMS** (secondary

ion mass spectrometry). The ISO TC 201 committee also has a subcommittee that deals with glow discharge spectroscopies. Whilst these latter methods have been used more for bulk analysis than surface analysis, the information they produce comes from the surface of the sample as that surface moves into the sample, and so they have been finding applications in depth profiling studies.

One thing that is common to all of these surface chemical analysis techniques is that they are vacuum-based methods. In other words, the sample has to be loaded into a high or ultrahigh vacuum system for the analysis to be carried out. With the one exception of glow discharge optical emission spectroscopy (**GDOES**), where the analysis relies upon the detection of photons, all of the techniques also depend upon the detection of charged particles. This requirement for vacuum operation necessarily imposes limits on the types and sizes of samples that can be analyzed, although of course instruments capable of handling semiconductor wafers do exist. The quality of the vacuum environment around the sample can also affect the quality of the analysis, especially with regard to the detection of elements that exist in the atmosphere around us. The size and complexity of surface chemical analysis equipment has arguably tended to limit the wider use of these powerful methods.

18.1 Electron Spectroscopy

In the electron spectroscopies, Auger and **XPS**, the surface of the sample is probed by an exciting beam which

causes electrons to be ejected from the atoms in the sample. These electrons are collected and their ener-

gies analyzed. The two techniques are similar but subtly different.

18.1.1 Auger Electron Spectroscopy

In Auger, a beam of electrons is used to excite the sample. During the interaction of the primary electron beam with the sample atoms, core electrons are knocked out, creating vacancies in the inner electron shells. Electrons from outer shells can fall into the vacancy, thus leaving the atom in an unstable state and, in order to return to equilibrium, the excess energy the atom possesses can be dissipated in one of two ways: either by the emission of an X-ray photon with a characteristic energy (the basis of energy- or wavelength-dispersive X-ray analysis), or by the emission of a third electron (the Auger electron), with an energy determined by the difference in energy between the original core state and those of the two other levels involved. Clearly these energies are uniquely determined by the energy levels in the atom and thus provide a route for analysis. As three electrons are necessary for the Auger process to occur, AES is incapable of detecting hydrogen or helium, but all other elements produce characteristic Auger electrons. The energies of the Auger electrons can range from a few tens of electron volts to a few thousand electron volts. In this energy regime, electrons can only travel of the order of monolayers through a solid before an interaction occurs which causes a loss of energy, thus destroying the analytical information the electron possessed. It is this property which gives the Auger technique its surface sensitivity – although Auger electrons will be produced as far into

the material as the primary beam can penetrate, only those produced in the top few monolayers can escape with their characteristic energy intact. The Auger electrons excited deeper into the sample lose energy before escaping and contribute to a background signal, as do the scattered primary electrons and the initial core electrons ejected at the start of the process. These scattered electrons produce a background signal against which the Auger electrons must be detected; this limits the analytical sensitivity that can be achieved by Auger. This is also why Auger spectra are sometimes displayed as the differential of the number of electrons against energy, because the small Auger peaks are more rapidly varying functions than the larger, slowly changing background signal and hence are enhanced by the differentiation process. Figure 18.1 shows an Auger spectrum from GaInAsP, where the spectrum plotted as the number of electrons as a function of energy is compared to the differential of the number of electrons as a function of energy.

As the number of Auger electrons produced is proportional to the number of atoms excited, Auger offers the ability to perform quantitative as well as qualitative analyses, although some form of calibration is required, either through the use of local reference materials or instrument calibration and standard databases. So Auger offers quantitative analysis for all elements from lithium to uranium from layers only a few atoms in thickness. What gives Auger an extra dimension is the ability to profile into the sample by removing the outermost surface layers with an inert gas ion beam (usually argon) in order to expose the layers below. This sputter depth profiling is the inverse of the sputter deposition widely used to deposit thin layers of material. Argon is the most widely used ion beam in Auger depth profiling, as its effects are physical rather than chemical, although it should be noted that some chemicals can be modified by the sputtering process. For example, some metal oxides can be reduced by sputtering while others are not, and so any chemical state data inferred from atomic compositions in sputter depth profiles should be treated with caution. Physical effects can also occur, for example atomic mixing and the development of surface topography, which can distort the shape of buried features.

One of the great advantages of Auger is that, as the excitation is provided by electrons, the primary beam can be easily focused and scanned over the surface of the sample. By detecting the scattered electrons, a physical image of the sample is produced as in the scanning electron microscope, and maps of elemental distributions can be obtained by detecting the Auger signal as

Fig. 18.1 Auger spectrum from GaInAsP, shown as the number of electrons and the differential of the number of electrons as a function of energy

Fig. 18.2 Optical image and Auger maps of a stained aluminium bond pad

a function of beam position. These elemental maps can be time-consuming to acquire but can be useful when making a point or illustrating a book chapter; however, for practical analyses it is often adequate to identify the feature of interest from the physical image. Figure 18.2 shows aluminium and oxygen Auger maps from a contaminated bond pad. In the region of the contamination, the aluminium signal is reduced and the oxygen signal is higher compared with the uncontaminated regions.

In terms of hardware, Auger systems can be stand-alone systems comprising an electron beam column, an electron energy analyzer, an inert gas ion gun and sample handling stage and an associated vacuum chamber (or chambers), or form a part of a multitechnique system with X-ray sources for XPS analysis or a mass spectrometer for basic SIMS studies.

18.1.2 X-Ray Photoelectron Spectroscopy (XPS)

XPS is very similar to Auger in terms of the instrumentation and physics involved. The primary excitation, as the name implies, is, in this case, a beam of X-rays. The X-rays, often magnesium or aluminium $K\alpha$, eject core electrons from the surface atoms by the photoelectron effect. The kinetic energy of the emitted photoelectrons will be equal to the difference between the X-ray photon energy and the core level binding energy, and thus

will be less than ≈ 1100 eV or ≈ 1400 eV for magnesium and aluminium $K\alpha$ respectively. So, as with Auger, the mean free paths of the photoelectrons are of the order of monolayers in solid materials. As a core level vacancy is produced by the excitation, Auger electrons will also be present in the XPS spectra but, by convention, Auger spectroscopy refers to the electron-excited situation. Whereas in Auger electron spectroscopy the electron energy is usually referred to in terms of the electron's kinetic energy, in XPS the electron binding energy is usually plotted as the ordinate in the spectra. This means that, whatever X-ray excitation is used, be it magnesium, aluminium or a more exotic material, the photoelectrons will appear at the same binding energy in the spectra but the apparent positions of the Auger peaks will change (on the binding energy scale) as their kinetic energy is independent of the excitation source. There are no scattered primary electrons (which are always present in Auger spectra) in the XPS spectra, so these spectra have better signal-to-background, and the photoelectron peaks are easily distinguished against the background arising from scattered photoelectrons produced deeper into the sample and other secondary processes.

As the problem of focusing electron beams is much simpler than focusing X-ray beams, XPS is perceived as a large-area technique, whereas Auger is the technique of choice for small area analysis. However, the relentless advances made in the performance and design of instruments means that XPS instruments can achieve spatial resolutions of the order of 1 to $10\mu\text{m}$. In XPS no charge is brought to the sample by the primary excitation, and so insulating samples are easier to analyze with XPS than with Auger; also, the photoelectron peaks show small energy differences in the peaks positions depending upon the local chemical environment of the atom from which they originated, the so-called chemical shift. While chemical shifts are present in some Auger peaks, this is the exception rather than the rule, and XPS is the technique of choice where information on the local chemical state of the surface is required. The physics of the XPS process is probably even better understood than the Auger process, and quantification of the spectra is relatively routine.

As with Auger, composition depth profiles can be produced by sputtering the surface of the sample with an inert gas ion beam. Again caution is advised when interpreting chemical state information from a surface that has been subject to ion bombardment. With both of the electron spectroscopies it is the surface of the sample that remains after sputtering that is analyzed in a depth profile, and there are two factors to be aware

of (if not more). Once the passivating surface layer has been sputtered away, the surface of the sample may become chemically active and getter residual gas from the vacuum system. If the sample is a multicomponent material, one component may have a higher sputtering rate than the other, so as the sputtering process proceeds the surface will become depleted in the higher sputtering rate material. This process will continue until an equilibrium state is reached where the material leaving the surface is in the same ratio as the bulk composition; the

corollary of this is that the surface will be enriched in the lower sputter rate material and so the composition of the material as measured by either *XPS* or Auger will be in error unless this effect is understood and accounted for.

Both Auger and *XPS* are capable of detecting all elements from lithium to uranium (and beyond), and have sensitivities in the parts per hundred to parts per thousand regime. The responses vary from element to element but typically sensitivities remain within an order of magnitude or so between elements.

18.2 Glow-Discharge Spectroscopies (GDOES and GDMS)

These are two apparently similar but quite unrelated techniques that rely upon glow discharges as the excitation source. In glow discharge optical emission spectroscopy (*GDOES*) a high-pressure glow discharge is used to sputter material from the surface of a sample, and this sputtered material is detected by the optical emissions it produces in the glow discharge. In glow discharge mass spectrometry (*GDMS*), a low pressure dc glow discharge is used to sputter material from the sample surface and ionized material from the discharge is extracted into a mass spectrometer for analysis.

GDOES is probably the simplest of all the surface chemical analysis techniques, at least as far as the vacuum requirements are concerned. There is no complex vacuum system, as needed for all of the other methods, and the sample itself sits with atmospheric pressure on one side of it while the opposite face acts as one

electrode of a glow discharge cell that is pumped by a simple vacuum pump. A flow of high-purity argon gas flows through the cell, providing the sputtering and discharge gas and purging the cell of impurities and material removed from the sample. A window at the other end of the discharge cell transmits light from the discharge into an optical spectrometer. By using a spectrometer with a number of photomultiplier detectors, prepositioned at the known wavelengths of the expected element emission lines, data from a large number of elemental channels can be collected in parallel, making *GDOES* an extremely efficient analytical system. A scanning spectrometer can also be included in the instrument to provide a continuous spectral scan to detect emission lines from elements other than those built into the instrument, but this is, of course, a serial detection device and the advantages of parallel acquisition are lost.

Traditionally *GDOES* has been widely used for the analysis of metals and coatings on metals, but it is currently also finding application in the area of semiconductor materials. With the development of radio frequency glow discharge sources, the technique is capable of analyzing insulators, and with the high sputtering rates available, it can depth profile tens of μm into dielectric layers. With fast electronics and parallel detection, thin oxide layers can also be profiled. The sensitivity of the *GDOES* technique lies between that of Auger or *XPS* and that of *SIMS*. One potential weakness of the method is that the technique has no spatial resolution and the analysis area is millimeters in diameter. It is thus useful for large-area plain samples, but cannot be used with patterned material or to probe small features. The technique is useful for bulk analysis, but it is the ability to depth-profile into material, providing an insight into layer structures, that is its greatest appeal. However, because the technique has no ability to dis-

Fig. 18.3 *GDOES* depth profile through a *DWDM* multilayer glass structure

criminate where the analytical signal is coming from, the quality of the depth profiles produced will be compromised by crater edge effects. In other words, while most of the analytical signal will originate from the bottom of the sputtered crater, there will always be some information that comes from the crater side wall. The consequence of this is that, with layered structures, layers closer to the surface will appear to tail into layers beneath them, even though the interface between the layers is abrupt. This effect can be seen in the depth profile shown in Fig. 18.3, which shows a GDOES profile into a DWDM structure.

Glow discharge mass spectrometry (GDMS) is a considerably more complex technique, at least from an instrumental point of view. Originally developed as a method of bulk analysis, GDMS is probably the most sensitive, in terms of the detection limit achievable, of all of the techniques being considered here. As with GDOES, in GDMS the sample forms one electrode in a simple glow discharge cell. However, in the case of GDMS, the discharge cell is mounted within a high-vacuum system. In its original form, the sample (typically be 1 mm² by about 15 mm long) is placed in the center of a cylindrical cell into which argon is leaked at low pressure. By applying a dc voltage between the sample and the cell, an argon plasma is created which

sputters the outside of the sample, removing material. This material, some of which is ionized but the majority of which is neutral as it leaves the surface, is ionized by a variety of processes as it passes through the glow discharge plasma. These ions are then accelerated into a high-resolution magnetic sector mass spectrometer where they are mass-analyzed and counted. Instruments can also be based on quadrupole mass spectrometers, but it is the magnetic sector instruments which offer the greater sensitivity. By sweeping the mass spectrometer through a range of masses, which can cover the entire periodic table, the major, minor and trace elements present in a sample can be determined. GDMS is a particularly powerful method of detecting the trace elements present in bulk semiconductor materials at levels down to parts per billion.

It is also possible to analyze flat, rather than matchstick-shaped, samples in GDMS. Just as in GDOES, the flat sample is positioned at the end of the discharge cell, and a cylindrical crater is etched into the sample surface. As with GDOES, with GDMS there is no spatial resolution, and the depth information from layered structures will be distorted by crater edge effects and loss of crater base flatness as it is not possible to discriminate between ions produced from the base of the crater and those produced from the sidewalls.

18.3 Secondary Ion Mass Spectrometry (SIMS)

SIMS is probably the most powerful and versatile of all of the surface analysis techniques and comes in the widest variety of instrumentations, from big, stand-alone instruments to bench-top instruments and add-ons to electron spectrometers. SIMS can offer chemical identification of submonolayer organic contamination, measurement of dopant concentrations, and can produce maps and depth profile distributions from nanometers to tens of μm in depth. However, no one instrument is going to be capable of all of these tasks, and even if it could it would not be able to achieve all of them at the same time.

SIMS, in its simplest form, requires an ion gun and a mass spectrometer. The sample is placed in a vacuum chamber and ions from the ion gun sputter the sample surface. Material is sputtered from the sample surface and some of this will be ionized, although in most cases the major part of the sputtered material will be in the form of a neutral species. The ionized component of the sputtered material is mass-analyzed with the mass spectrometer.

The technique has evolved in various directions from this common origin to produce a variety of subtly different variants of the SIMS technique, including dynamic SIMS (DSIMS), static SIMS (SSIMS) and time of flight SIMS (ToFSIMS), each of which has its own distinct attributes. There are three main types of mass spectrometer used for SIMS analysis: the magnetic sector, the quadrupole and the time of flight, ToF. Dedicated depth-profiling SIMS machines, dynamic SIMS instruments, tend to employ either magnetic sector or quadrupole mass spectrometers. Magnetic sector instruments offer high transmission and high mass resolution capabilities, useful for separating adjacent mass peaks with a very small mass difference, for example ³¹P from ³⁰SiH. Quadrupole mass spectrometers offer ultrahigh vacuum compatibility and, as well as being used in DSIMS instruments, smaller versions are also found as add-ons to Auger/XPS instruments and bench-top instruments. Time of flight instruments are remarkably efficient in their use of material in that the entire mass spectrum is sampled in parallel, whereas in the

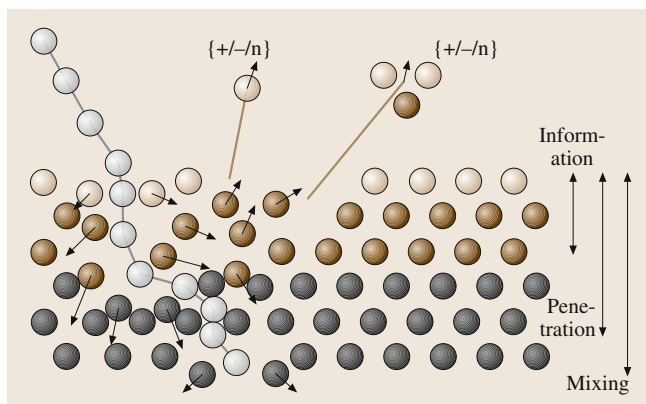

Fig. 18.4 Schematic diagram of the SIMS process

magnetic sector and quadrupole instruments the spectrum is produced by sequentially scanning through the mass range of interest. ToFs can also offer high mass resolution but profile relatively slowly because it is necessary to use a pulsed ion beam with a low duty cycle. Whilst static SIMS can be carried out on either a quadrupole or magnetic sector instrument, the ToF-based instruments are more suited to the task as less material is used in the course of the analysis. However, when dynamic SIMS, where only a few elements need to be monitored, is the goal, the magnetic sector or quadrupole instrument is the appropriate choice, although ToF machines can be used for shallow profiling.

Fig. 18.5 Static SIMS spectrum from a thin film of poly(dimethylsilicone)

Figure 18.4 shows a schematic diagram of the basis of these SIMS techniques. Ions from the ion gun bombard the sample surface and transfer momentum to the atoms in the sample creating a collision cascade. This cascade distributes the energy of the incoming ion amongst the atoms in the sample, causing them to be displaced from their original sites, possibly breaking some bonds between atoms whilst creating others. The bombarding ion also can become implanted into the target material, modifying the chemistry of the material in the process. None of this is peculiar to SIMS – it happens in any sputtering process, be it in Auger depth-profiling, GDMS analysis or sputter deposition systems. It is probable that some of the energy deposited in the sample will cause atoms or molecules to be ejected from the surface of the sample, and those atoms or molecules that leave the surface as ions can be collected and detected by the mass spectrometer.

In the early stages of sputtering, the atoms and molecules sputtered from the surface will originate from areas of virgin surface – in other words from sites that have not yet been damaged by the primary ion – and thus carry with them information about the chemistry of the outer molecular layers of the sample. As the sputtering process proceeds, the probability of the sputtered particles being emitted from an area that has been modified by earlier ion impacts increases. Thus, at the start of the process the sputtered particles are characteristic of the virgin surface, but they will eventually become characteristic of the ion beam-modified surface.

Static SIMS is concerned with the measurement of the sputtered molecules produced at the start of the process, where information about the surface chemistry of the sample can be obtained. In SSIMS a very low dose of primary ions is used, typically less than 10^{13} primary ions per square centimeter, so that there is a very low probability that the ions that are detected come from damaged material. Used in this way, SIMS can be used to identify organic contamination on surfaces and obtain information about the molecular structure of the sample. Figure 18.5 shows a typical SSIMS mass spectrum from poly(dimethyl silicone), a common surface contaminant, which can be recognized by prominent peaks in the mass spectrum at masses 73, 133, 147, 207 and 221, which originate from fragmentation of the parent molecule ($\text{CH}_3 - \text{Si}(\text{CH}_3)_2 - \text{O} - \text{Si}(\text{CH}_3)_2 - \text{O} - \dots - \text{Si}(\text{CH}_3)_2 - \text{CH}_3$).

Whilst the abundance of molecular fragments that can be produced by the sputtering process is of great value for revealing chemical information about the

sample surface in the SSIMS context, it can also be something of a problem when carrying out elemental analysis of trace impurities in simple matrices. For example, the spectrum shown in Fig. 18.6a, from an unknown Ga-based material, illustrates the number and complexity of molecular species produced by the SIMS process, which can make interpretation difficult. Fortunately, the distribution of the number of secondary ions with energy is different between atomic ions and molecular ions. The atomic ions, in general, have a broader energy distribution than the molecular ions, and its energy distribution tends to become sharper as the complexity of the molecular ion increases. For example, Fig. 18.7 shows the ion energy distributions of the Si^+ , Si_2^+ and Si_3^+ ions, illustrating the narrower energy distributions of the molecular ions. Thus, by selecting the ion energy range from which the spectrum is recorded, the molecular information can be suppressed, allowing the elements present in the material to be identified, see Fig. 18.6b.

The intensities of the peaks in the SIMS mass spectra reveal more about the relative ionization probability and instrument transmission function than the number of species of that mass on the sample surface. The signals that are measured in SIMS are proportional to the numbers of ions produced, and this is not simply related to the amount of material present. The degree of ionization can vary enormously from element to element and matrix to matrix. For example, the numbers of positive ions formed by the inert gas bombardment of clean metal samples can be several orders of magnitude lower than the numbers produced from oxidized surfaces of the same metals under identical bombardment conditions. Clearly it is not the concentration of the metal atoms on the surface that is important, as there will be fewer metal atoms in the oxide layer than in the pure metal. It is the presence of oxygen that increases the ionization probability for material leaving the surface as positive ions.

In SSIMS, the chemical nature of the primary ion species is of relatively little consequence in terms of its effect on the number of ions produced by the surface, but in DSIMS, where it is the deliberately modified surface that is of interest, oxygen ion beams are widely used for analyses of electropositive species. Figure 18.8 shows how the silicon matrix signal from a silicon wafer with a native oxide layer behaves as the sputtering process proceeds. Initially there is a strong signal from silicon as the surface oxide layer is still present on the sample surface. The signal then falls as the oxide layer is sputtered away, and then slowly recovers in intensity as

Fig. 18.6 SIMS mass spectrum from an unknown sample *top panel* without energy filtering, *bottom panel* with energy filtering

oxygen from the primary ion beam is implanted into the silicon surface. Eventually a steady state is reached where the material that is being sputtered is constant-composition oxygen-implanted silicon. The thickness of this transient region will depend upon the energy and angle of incidence of the primary oxygen ion beam. The higher the ion beam energy, the thicker the transient region. In the transient region the sputtering rate of the material and the ionization probability may well be changing, and precise quantification in this part of the

Fig. 18.7 The ion energy distributions of Si^+ , Si_2^+ and Si_3^+ ions

Fig. 18.8 The evolution of the Si^+ signal from a clean silicon wafer as a function of sputtering time with an oxygen primary ion beam, showing the decay of the surface oxide signal and the build-up of the implanted oxide layer

profile may be difficult. This is of particular importance when the features of interest are very close to the surface and within the transient region. The technological importance of shallow structures has driven the develop-

Fig. 18.9a,b Mass spectra from a GaAs wafer recorded (a) using Cs^+ primary ion bombardment and negative secondary ion detection, and (b) using O_2^+ primary ion bombardment and positive secondary ion detection

ment of very low energy primary ion beam columns to enable the characterization of shallow implants.

Clearly, as is illustrated in Fig. 18.8, the number of positive ions produced in the sputtering process depends upon the concentration of oxygen in the sample surface. In order to maximize the positive secondary ion yield, the sample surface needs to be saturated with oxygen, and this can be achieved with normal-incidence primary ion beams or by deliberately allowing oxygen to flood the sample surface as well as using an oxygen primary ion beam. In the example shown in Fig. 18.8, the primary ion beam was incident at approximately 45° and so complete oxidation of the silicon surface was not achieved, meaning that the silicon and oxygen signals in the equilibrium region are not as high as from the fully oxidized native oxide layer.

Not all species prefer to form positive ions in the sputtering process; some prefer to produce negative ions. Oxygen is a case in point, and indeed it would be difficult to conduct an analysis for oxygen using an oxygen beam. For electronegative species, it turns out that high

Fig. 18.10a,b Reference sample of boron ion-implanted silicon, (a) raw data profile and (b) quantified depth profile

negative secondary ion yields can be achieved if the surface is sputtered using cesium ions. An illustration of the relative ion yields of gallium and arsenic as positive and negative ions from a gallium arsenide surface with oxygen and cesium ion bombardment are shown in Fig. 18.9. Some species can be reluctant to produce either positive or negative secondary ions, but in some cases (such as zinc), good sensitivity can be achieved by using cesium ion bombardment and monitoring the cesium–element molecular ion, CsZn^+ in the case of zinc.

Despite the wide variations in secondary ion yields from element to element and matrix to matrix, the quantification of impurities in semiconductors can be relatively straightforward when reference materials are used. For example, Fig. 18.10a shows a raw data depth profile of ^{11}B ions implanted in silicon; knowing the areal dose of ions implanted into the sample and the depth of the crater sputtered into the sample, it is a relatively simple task (usually buried in the instrument software) to convert boron counts into concentrations

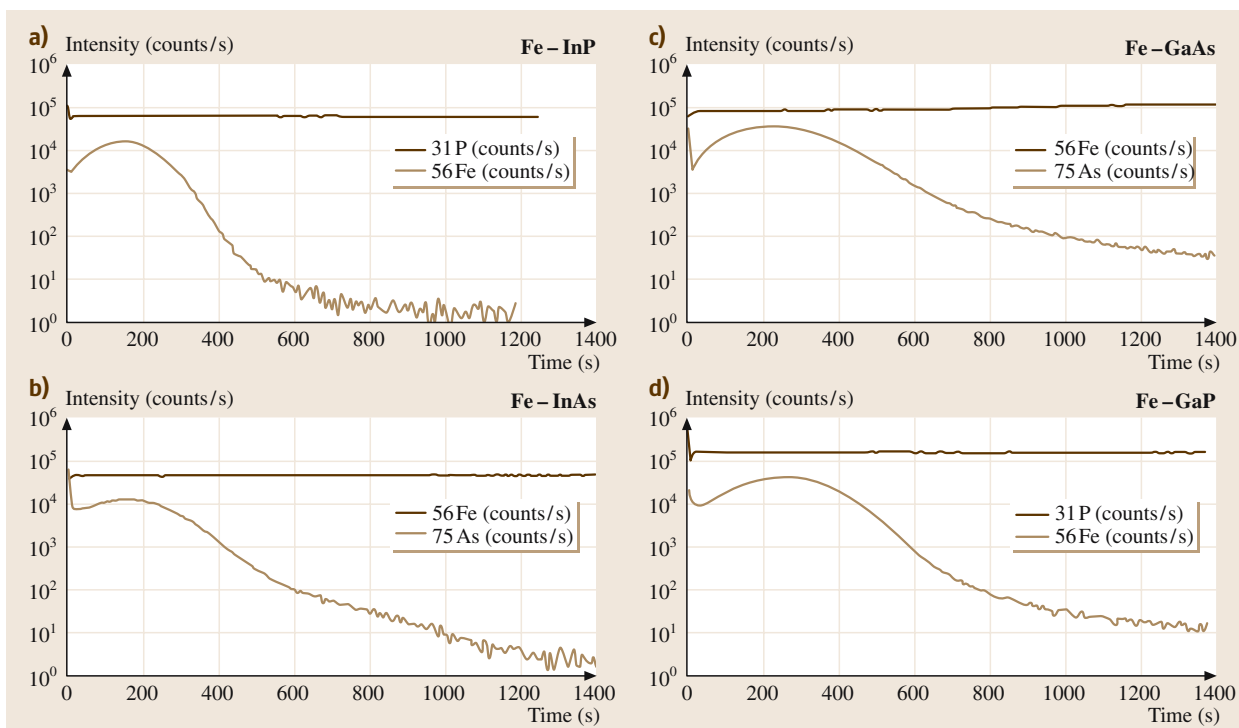

Fig. 18.11 (a)–(d) show iron profiles, recorded under identical conditions, from implants into InP, InAs, GaAs and GaP, respectively

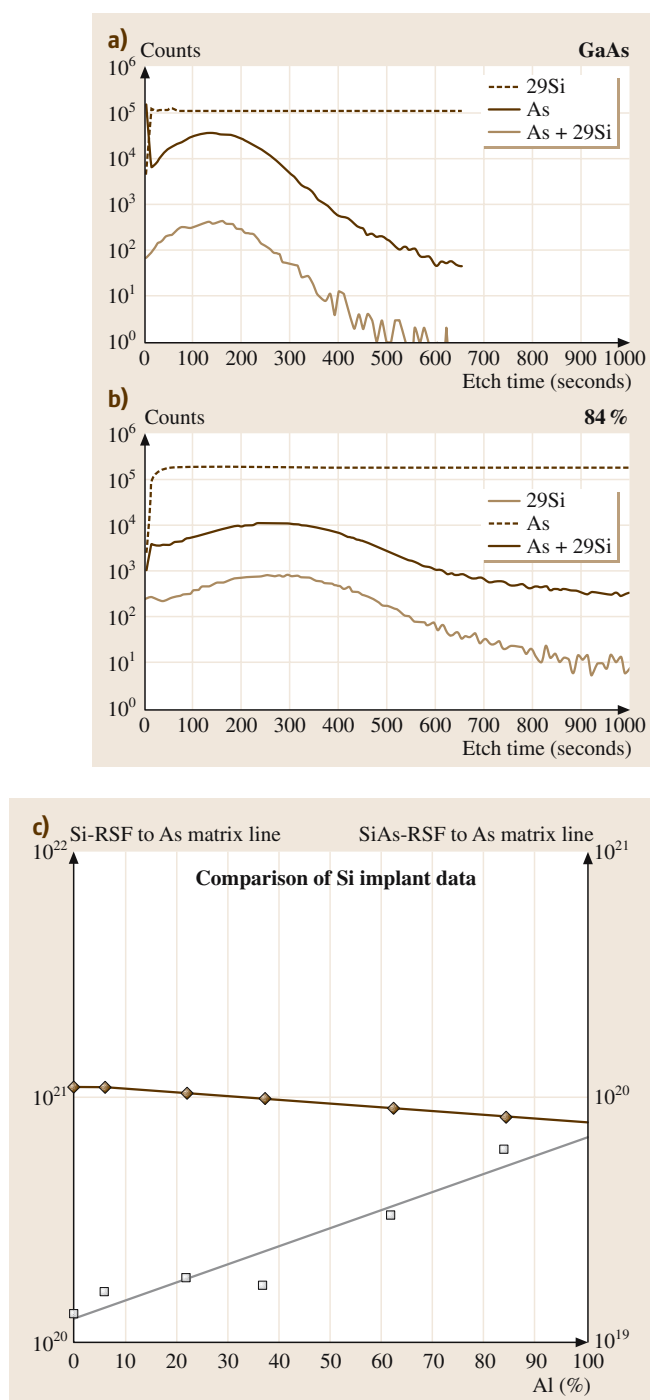

Fig. 18.12a–c Depth profiles of silicon as Si⁻ and AsSi⁻ in (a) GaAs and (b) Ga_{0.16}Al_{0.84}As, and (c) variation in relative sensitivity factor as a function of aluminium content

(Fig. 18.10b). By recording a signal from the matrix element, either during the profile as in Fig. 18.10a, or in the crater after the profile, a relative sensitivity factor for the analyte (boron) in the matrix of interest (silicon) can be obtained which can then be used to determine the concentration of that analyte in another sample of the same matrix. Errors or uncertainties can arise from both the crater depth measurement and the implanted dose measurement. At the time of writing, there are only three metrologically traceable reference samples for SIMS (boron, arsenic and phosphorus in silicon) produced by NIST in the USA. For other species and other matrices, the analyst must rely upon locally produced materials with no traceability.

Care must be exercised when the analyte of interest is present in different matrices. For example, Figs. 18.11a–c and d show iron profiles, recorded under identical conditions (positive ion detection with O₂⁺ primary ion bombardment), from implants into InP, InAs, GaAs and GaP produced in the same implant run. While the relative sensitivity of iron to the phosphorus matrix signal is the same for InP and GaP matrices, there is a variation of the order of 20% in the arsenide matrices. The useful ion yield of iron (the total number of ions produced as a fraction of the number of atoms present) increases approximately four-fold in the gallium-based matrices compared to the indium-based matrices. The profile in the GaAs sample, Fig. 18.11c, also shows a further complication: the arsenic matrix signal increases at about 1000 s into the profile. This could be interpreted as an upwards drift in the primary ion beam current, but it is actually caused by roughening of the GaAs surface as a result of the sputtering process. This effect is more common with oxygen primary ion bombardment than with cesium bombardment, and it has been shown that it is possible to reduce such effects by rotating the sample during analysis. Not only does the roughening modify the analytical signal, it also causes an apparent broadening of sharp features present in the sample as the surface roughness is convoluted with the feature width. The problems associated with sputter-induced roughness can become more severe when dealing with metal films but, once again, can be overcome by sample rotation.

Another example of how relative sensitivity factors vary with the matrix is shown in Fig. 18.12. Here a comparison is shown between the behavior of the Si⁻ and AsSi⁻ signals as the matrix is changed from GaAs to Ga_{0.16}Al_{0.84}As. Molecular signals such as AsSi⁻ are sometimes used to give increased signal compared to the atomic signal but, as in the example shown, the backgrounds are often similarly increased. What is inter-

Fig. 18.13 Depth profiles of As in Si for different analytical conditions

esting here is that whilst the ion yields from the Si^- and As^- signals increase, but at different rates with increasing Al content, the AsSi^- signals decrease. Ideally the analyst needs to be aware of, and able to take account of, such variations in response. Simply using the relative sensitivity factor derived for a GaAs matrix and applying this to high Al content material using a point-by-point normalization to the As^- signal can lead to a 30% overestimate of the silicon content. However, monitoring the AsSi^- signal instead and using the same normalization procedure can underestimate the silicon content by over 350%.

With an ideal analytical technique the analytical signal will vary linearly with concentration over all concentrations. With SIMS, for uniform matrices, the measured signal is indeed linear with concentration for dilute systems. However, once the analyte concentration begins to exceed a few percent of the material, the signal may begin to vary in a nonlinear way with concentration. Thus, whilst SIMS is the ideal technique for

quantifying minor and trace contaminants, it is less than ideal for determining matrix element concentrations. The most successful method of measuring elemental concentrations at high levels was achieved by monitoring the cesium molecular species (CsAl^+ and CsGa^+ and CsAs^+) in GaAlAs. In GaAlAs the ($\text{CsAl}^+/\text{CsAs}^+$) and ($\text{CsGa}^+/\text{CsAs}^+$) ratios do vary linearly with the Al content.

Returning to practical analysis, another factor that needs to be considered in relation to DSIMS, and one that is related to the primary bombarding particles, is atomic mixing. The primary ions used to bombard the surface transfer momentum to the atoms in the sample surface. While some of the atoms will be sputtered from the surface, others will be driven deeper into the sample, thus broadening any concentration distributions that were present within the original sample. The higher the primary ion beam energy, the more severe the atomic mixing. Consequently, as the need to analyze shallower and shallower structures has increased, there has been a move to develop instruments that use lower bombardment energies and sources producing polyatomic ions. A simple example of how the analytical conditions can cause profile distortion is shown in Fig. 18.13. These profiles were recorded from an arsenic-implanted and annealed polysilicon layer on a thin oxide on silicon. Using an oxygen primary ion beam striking the surface at oblique incidence with an impact energy of 5.5 keV (a) produces a profile that shows a spike followed by a rapid fall at the polysilicon/oxide interface. Using a cesium primary ion beam striking the surface at close to normal incidence with an impact energy of 14.5 keV (b) gives a much better detection limit with smaller interface spikes but with a much less abrupt fall in the arsenic signal. Profile (c), which uses the same bombardment conditions as profile (a) but combined with oxygen flooding of the sample surface (and consequently took longer to acquire), shows good agreement with profile (b) in terms of the size of the interface spike – which is exaggerated in profile (a) because of the increased ion yield from the oxide layer compared to the polysilicon – and good agreement with profile (a) in terms of the decay of the arsenic signal in the interface region, and has better sensitivity than profile (a) but less than profile (b). These profiles demonstrate the trade-off that the analyst must make when choosing analysis conditions.

18.4 Conclusion

The various surface chemical analysis techniques have their own strengths and weaknesses. No one method is suitable for all of the tasks the analyst faces; sometimes one technique is sufficient to address the problem

at hand, sometimes a combination of them is required. However, the approach should be successful if the technique(s) is (are) fit for the purpose of the task.

19. Thermal Properties and Thermal Analysis: Fundamentals, Experimental Techniques and Applications

The chapter provides a summary of the fundamental concepts that are needed to understand the heat capacity C_p , thermal conductivity κ , and thermal expansion coefficient α_L of materials. The C_p , κ , and α of various classes of materials, namely, semiconductors, polymers, and glasses, are reviewed, and various typical characteristics are summarized. A key concept in crystalline solids is the Debye theory of the heat capacity, which has been widely used for many decades for calculating the C_p of crystals. The thermal properties are interrelated through Grüneisen's theorem. Various useful empirical rules for calculating C_p and κ have been used, some of which are summarized. Conventional differential scanning calorimetry (DSC) is a powerful and convenient thermal analysis technique that allows various important physical and chemical transformations, such as the glass transition, crystallization, oxidation, melting etc. to be studied. DSC can also be used to obtain information on the kinetics of the transformations, and some of these thermal analysis techniques are summarized. Temperature-modulated DSC, TMDSC, is a relatively recent innovation in which the sample temperature is ramped slowly and, at the same time, sinusoidally modulated. TMDSC has a number of distinct advantages compared with the conventional DSC since it measures the complex heat capacity. For example, the glass-transition temperature T_g measured by TMDSC has almost no dependence on the thermal history, and corresponds to an almost step life change in C_p .

The new Tzero DSC has an additional thermocouple to calibrate better for thermal lags inherent in the DSC measurement, and allows more accurate thermal analysis.

The selection and use of electronic materials, one way or another, invariably involves considering such thermal properties as the specific heat capacity (c_s), thermal conductivity (κ), and various thermodynamic and structural transition temperatures, for example, the melting or fusion temperature (T_m) of a crystal, glass transformation (T_g) and crystallization temperature (T_c) for glasses and amorphous polymers. The thermal expansion coefficient (α) is yet another important material property that comes into full play in applications of electronic mater-

ials inasmuch as the thermal expansion mismatch is one of the main causes of electronic device failure. One of the most important thermal characterization tools is the differential scanning calorimeter (DSC), which enables the heat capacity, and various structural transition temperatures to be determined. Modulated-temperature DSC in which the sample temperature is modulated sinusoidally while being slowly ramped is a recent powerful thermal analysis technique that allows better thermal characterization and heat-capacity measurement. In addition, it

can be used to measure the thermal conductivity. The present review is a selected overview of thermal properties and the DSC technique, in particular MTDSC. The overview is written from a materials science perspective with emphasis on phenomenology rather than fundamental physics.

19.1 Heat Capacity

19.1.1 Fundamental Debye Heat Capacity of Crystals

The heat capacity of a solid represents the increase in the enthalpy of the crystal per unit increase in the temperature. The heat capacity is usually defined either at constant volume or at constant pressure, C_V and C_P , respectively. C_V represents the increase in the internal energy of the crystal when the temperature is raised because the heat added to the system increases the internal energy U without doing mechanical work by changing the volume. On the other hand C_P represents the increase in the enthalpy H of the system per unit increase in the temperature. Thus,

$$C_V = \left(\frac{\partial H}{\partial T} \right)_V = \left(\frac{\partial U}{\partial T} \right)_V \quad \text{and} \quad C_P = \left(\frac{\partial H}{\partial T} \right)_P. \quad (19.1)$$

The exact relationship between C_V and C_P is

$$C_V = C_P - \frac{T\alpha^2}{\rho K}, \quad (19.2)$$

where T is the temperature, ρ is the density, α is the linear expansion coefficient and K is the compressibility. For solids, C_V and C_P are approximately the same. The increase in the internal energy U is due to an increase in the energy of lattice vibrations. This is generally true for all solids except metals at very low temperatures where the heat capacity is due to the conduction electrons near the Fermi level becoming excited to higher energies. For most practical temperature ranges of interest, the heat capacity of most solids is determined by the excitation of lattice vibrations. The molar heat capacity C_m is the increase in the internal energy U_m of a crystal of Avogadro's number N_A atoms per unit increase in the temperature at constant volume, that is, $C_m = (dU_m/dT)_V$. The Debye heat capacity is still the most successful model for understanding the heat capacity of crystals, and is based on the thermal excitation of lattice vibrations, that is phonons, in the crystal [19.4];

The thermal properties of a large selection of materials can be found in various handbooks [19.1, 2]. In the case of semiconductors, *Adachi's* book is highly recommended [19.3] since it provides useful relationships between the thermal properties for various group IV, II–V and II–VI semiconductors.

it is widely described as a conventional heat capacity model in many textbooks [19.5, 6]. The vibrational mean energy at a frequency ω is given by

$$\bar{E}(\omega) = \frac{\hbar\omega}{\exp(\frac{\hbar\omega}{k_B T}) - 1}, \quad (19.3)$$

where k_B is the Boltzmann constant. The energy $\bar{E}(\omega)$ increases with temperature. Each phonon has an energy of $\hbar\omega$ so that the phonon concentration in the crystal increases with temperature. To find the internal energy due to all the lattice vibrations we must also consider how many vibrational modes there are at various frequencies. That is, the distribution of the modes over the possible frequencies: the spectrum of the vibrations. Suppose that $g(\omega)$ is the number of modes per unit frequency, that is, $g(\omega)$ is the vibrational density of states or modes. Then $g(\omega)d\omega$ is the number of vibrational states in the range $d\omega$. The internal energy U_m of all lattice vibrations for 1 mole of solid is,

$$U_m = \int_0^{\omega_{\max}} \bar{E}(\omega)g(\omega)d\omega. \quad (19.4)$$

The integration is up to certain allowed maximum frequency ω_{\max} . The density of states $g(\omega)$ for the lattice vibrations in a periodic three-dimensional lattice, in a highly simplified form, is given by

$$g(\omega) \approx \frac{3}{2\pi^2} \frac{\omega^2}{v^3}, \quad (19.5)$$

where v is the mean velocity of longitudinal and transverse waves in the solid. The maximum frequency is ω_{\max} and is determined by the fact that the total number of modes up to ω_{\max} must be $3N_A$. It is called the *Debye frequency*. Thus, integrating $g(\omega)$ up to ω_{\max} we find,

$$\omega_{\max} \approx v(6\pi^2 N_A)^{1/3}. \quad (19.6)$$

This maximum frequency ω_{\max} corresponds to an energy $\hbar\omega_{\max}$ and to a temperature T_D defined by,

$$T_D = \frac{\hbar\omega_{\max}}{k}, \quad (19.7)$$

and is called the *Debye temperature*. Qualitatively, it represents the temperature above which all vibrational frequencies are executed by the lattice waves.

Thus, by using (19.3) and (19.5) in (19.4) we can evaluate U_m and hence differentiate U_m with respect to temperature to obtain the molar heat capacity at constant volume,

$$C_m = 9R \left(\frac{T}{T_D} \right)^3 \int_0^{T_D/T} \frac{x^4 e^x dx}{(e^x - 1)}, \quad (19.8)$$

which is the well-known Debye heat capacity expression.

Figure 19.1 represents the constant-volume Debye molar heat capacity C_m for a perfect crystal (19.8) as a function of temperature, normalized with respect to the Debye temperature. The well-known classical *Dulong–Petit rule* ($C_m = 3R$) is only obeyed when $T > T_D$. The Dulong–Petit (DP) rule is a direct consequence of the applications of Maxwell’s theorem of equipartition of energy and the classical kinetic molecular theory to vibrations of atoms in a crystal. Notice that C_m at $T = 0.5T_D$ is $0.825(3R)$, whereas at $T = T_D$ it is $0.952(3R)$. For most practical purposes, C_m is within 6% of $3R$ when the temperature is $0.9T_D$. For example, for copper $T_D = 315$ K and above about $0.9T_D$, that is above 283 K (or 10°C), $C_m \approx 3R$, as borne out by experiments. Table 19.1 provides typical values for T_D , and heat capacities for a few selected elements. At the lowest temperatures, when $T \ll T_D$, (19.8) predicts that $C_m \propto T^3$ and this is indeed observed in low-temperature heat capacity experiments on a variety of crystals. On the other hand, well-known exceptions are glasses, noncrystalline solids, whose heat capacity is proportional to $a_1T + a_2T^3$, where a_1 and a_2 are constants (e.g. [19.6, 7]).

It is useful to provide a physical picture of the Debye model inherent in (19.8). As the temperature increases from near zero, the increase in the crystal’s vibrational energy is due to more phonons being created and higher frequencies being excited. The phonon concentration increases as T^3 and the mean phonon energy increases as T . Thus, the internal energy increases as T^4 . At temperatures above T_D , increasing the temperature creates more phonons but does not increase the mean phonon energy and does not excite higher frequencies. All frequencies up to ω_{\max} have been now excited. The internal

Fig. 19.1 Debye constant-volume molar heat capacity curve. The dependence of the molar heat capacity C_m on temperature with respect to the Debye temperature: C_m versus T/T_D . For Si, $T_D = 625$ K, so at room temperature (300 K), $T/T_D = 0.48$ and C_m is only $0.81(3R)$

energy increases only due to more phonons being created. The phonon concentration and hence the internal energy increases as T ; the heat capacity is constant, as expected from (19.8).

In general terms, elements with higher atomic mass tend to have lower T_D , and their molar heat capacities are closer to the DP limit. Usually T_D is taken to depend on the temperature to accurately model the experimental C_p – T behavior; the dependence of T_D on T is only important at low temperatures, and can be neglected in most practical applications in engineering.

There are two important assumptions in the Debye theory. First is that all thermal excitations are lattice vibrations (i.e., involving phonons), which is usually the case in solids. Secondly, the interatomic potential-energy (PE) curve as a function of interatomic displacement x from equilibrium, is assumed to be parabolic, that is *harmonic* or symmetrical: $\text{PE} = \text{PE}_{\min} + (1/2)\beta x^2$, where β is a constant (the spring constant in the equation of net force versus displacement, $F = -\beta x$). Within the harmonic approximation, the lattice vibrations are *plane waves* that are independent of each other; they are vibrational normal modes of the lattice. Further, a symmetrical PE curve does not allow thermal expansion, which means that C_V

Table 19.1 Debye temperatures (T_D), heat capacities, thermal conductivities and linear expansion coefficients of various selected metals and semiconductors. C_m , c_s , κ , and α are at 25 °C. For metals, T_D is obtained by fitting the Debye curve to the experimental molar heat capacity data at the point $C_m = \frac{1}{2}(3R)$. T_D data for metals from [19.8]. and C_p are identical. However, the actual interatomic PE is anharmonic, that is, it has an additional x^3 term. It is not difficult to show that in this case the vibrations or phonons interact. For example, two phonons can *mix* to generate a third phonon of higher frequency or a phonon can decay into two phonons of lower frequency etc. Further, the anharmonicity also leads to thermal expansion, so that C_V and C_p are not identical as is the case in the Debye model. As a result of the anharmonic effects, C_p continues to increase with temperature beyond the $3R$ Dulong–Petit rule, though the increase with temperature is usually small.

19.1.2 Specific Heat Capacity of Selected Groups of Materials

Many researchers prefer to quote the heat capacity for one mole of the substance, that is quote C_m , and sometime express C_m in terms of R . The limit $C_m = 3R$ is the DP rule. It is not unusual to find materials for which C_m can exceed the $3R$ limit at sufficiently high temperatures for a number of reasons, as discussed, for example, by Elliott [19.6]. Most applications of electronic materials require a knowledge of the specific heat capacity c_s , the heat capacity per unit mass. The heat capacity per unit volume is simply c_s/ρ , where ρ is the density. For a crystal that has only one type of atom with an atomic mass M_{at} (g/mol) in its unit cell (e.g. Si), c_s is C_m/M_{at} expressed in J/K g.

While the Debye heat capacity is useful in predicting the molar heat capacity of a crystal at any temperature, there are many substances, such as metals, both pure

metals and alloys, and various semiconductors (e.g. Ge, CdSe, ZnSe etc.) and ionic crystals (e.g. CsI), whose room-temperature heat capacities approximately follow the simple DP rule of $C_m = 3R$, the limiting value in Fig. 19.1. For a metal alloy, or a compound such as $A_xB_yC_z$, that is made up of three components A , B and C with molar fractions x , y and z , where $x + y + z = 1$, the overall molar heat capacity can be found by adding individual molar heat capacities weighted by the molar fraction of the component,

$$C_m = xC_{mA} + yC_{mB} + zC_{mC}, \quad (19.9)$$

where C_{mA} , C_{mB} and C_{mC} are the individual molar heat capacities. Equation (19.9) is the *additive rule of molar heat capacities*. The corresponding specific heat capacity is

$$c_s = 3R/\bar{M}_{at}, \quad (19.10)$$

where $\bar{M}_{at} = xM_A + yM_B + zM_C$ is the mean atomic mass of the compound, and M_A , M_B and M_C are the atomic masses of A , B and C . For example, for ZnSe, the average mass $\bar{M}_{at} = (1/2)(78.96 + 65.41) = 72.19$ g/mol, and the DP rule predicts $c_s = 3R/\bar{M}_{at} = 0.346$ J/Kg, which is almost identical to the experimental value at 300 K.

The modern Debye theory and the classical DP rule that $C_m = 3R$ are both based on the addition of heat increasing the vibrational energy of the atoms or molecules in the solid. If the molecules are able to rotate, as in certain polymers and liquids, then the molar heat capacity will be more than $3R$. For example, the heat capacity of

molten Bi–BiI₂ mixture is more than the DP rule, and the difference is due to the rotational energies associated with various molecular units in the molten state [19.9].

The heat capacity of polymers are usually quite different than the expected simple Debye heat capacity behavior. Most polymers are not fully crystalline but either amorphous or semicrystalline, a mixture of amorphous and crystalline regions. Secondly, and most significantly, the polymer structures usually have a main chain (a backbone) and various side groups attached to this backbone. Stretching and possible bending vibrations and possible partial rotations of these side groups provide additional contributions to the overall heat capacity. The extent of freedom the main chain and side groups have in executing stretching and bending vibrations and rotations depends on whether the structure is above or below the glass-transition temperature T_g . (The glass-transition temperature is defined and discussed later.) Above T_g , the polymer structure is floppy and has sufficient free volume for various molecular motions to be able to absorb the added heat. The heat capacity is therefore larger above T_g than that below T_g , where the structure is frozen.

The heat capacity of most polymers increases with temperature. For most solid polymers (below the glass-transition temperature), the fractional rate of increase in the heat capacity with temperature follows

$$(1/C_P)(dC_P/dT) \approx 3 \times 10^{-3} \text{ K}^{-1} \quad (T < T_g) \quad (19.11)$$

to within about 5%. This empirical rule is particularly useful for estimating C_P at a desired temperature from a given value at another temperature e.g. at room temperature. For liquid polymers (above T_g) on the other hand, $(1/C_P)(dC_P/dT)$ is less ($\approx 1 \times 10^{-3} \text{ K}^{-1}$) and has a large variability (more than 30%) from polymer to polymer. There are various empirical rules for predicting the heat capacity of a polymer based on the backbone chain structure and types of side groups, as discussed by *van Krelen* and *Hoflyzer* [19.10]. The most popular is to simply sum heat capacity contributions per mole from each distinguishable molecular unit in the polymer structure's repeat unit. The heat capacity contribution from each type of identifiable molecular unit (e.g. $-\text{CH}_2-$ in the backbone or $-\text{CH}_3$ side group) in polymer structures are listed in various tables. For example, the molar heat capacity of polypropylene can be calculated approximately by adding contributions from three distinguishable units, CH_2 , CH and CH_3 in the repeating unit that makes up the polypropylene structure, as illustrated schematically in Fig. 19.2. Once the

Fig. 19.2 Molar heat capacity of solid polypropylene calculated from various distinguishable units in the repeat unit

contributions are added, the sum is 71.9 J/K mol. The molecular mass of the repeat unit corresponds to three C atoms and six H atoms, or to 42 g/mol so that the specific heat is 71.9 J/K mol/42 g/mol or 1.71 J/Kg, which is close to the experimental value. (Polypropylene is normally semicrystalline and its specific heat also depends on the crystalline-to-amorphous phase ratio.) The term *heat capacity per mole* in polymers normally refers to a mole of repeat units or segments in the polymer.

More rigorous characterization of the heat capacity of polymers tends to be complicated by the fact that most polymers are a mixture of the crystalline and amorphous phases, which have different C_P versus T characteristics, and the exact volume fractions of the phases may not be readily available. There have been a number of examples recently where the heat capacity characteristics of semicrystalline polymers have been critically examined [19.11]. A comprehensive overview of the heat capacity of polymers has been given by *Wunderlich* [19.12], which is highly recommended.

The overall or effective heat capacity of polymer blends can be usually calculated from the individual capacities and the volume fractions of the constituents. The simplest is a linear mixture rule in which individual capacities are weighted by the volume fraction and then summed.

The heat capacity of glasses depends on the composition and increases with temperature. There is a sharp change in the dependence of C_P on T through the glass-transition temperature T_g . For example, for zirconium, barium, lanthanum, aluminum, sodium (ZBLAN) glasses, C_m is 24 J/K mol below T_g and slightly less than $3R$. On the other hand, C_m is 38.8 J/K mol above T_g , and greater than $3R$. (The C_P change at T_g is discussed below.) The dependence of C_P on T below T_g has been modeled by a number of expressions dating back to the 1950s. For example, *Sharp* and *Ginther* [19.13] in 1951 proposed the following empirical expressions

Fig. 19.3 Normalized heat capacity $C_p(T)/C_p(298)$ versus $\ln(T/298)$ for various glasses. *Open square*: 12.5Na₂O, 12.5Al₂O₃, 75SiO₂; *solid circle*: 25MgO, 25CaO, 50SiO₂; *open triangle*: 33Na₂O, 67B₂O₃; *solid triangle*: 24BaO, 1Fe₂O₃, 75B₂O₃; *open diamond*: B₂O₃ (includes T_g); +30K₂O, 70GeO₂. Adapted from *Khalimovskaya-Churkina and Priven* [19.14]. The *solid straight line* is (19.14), whereas the *dashed line* is the experimental trend line

for the mean and true specific heat capacity c_m and c respectively, of oxide glasses in the range 0–1300 °C,

$$c_m = \frac{H_2 - H_1}{T_2 - T_1} = \frac{aT + c_o}{0.00146T + 1} \quad \text{and} \quad (19.12a)$$

$$c = \frac{dH}{dT} = \frac{aT + c_m}{0.00146T + 1} \quad (19.12b)$$

in which T is in °C, and a and c_o are calculated from the glass composition as described in the original paper [19.13]. The mean heat capacity in (19.12)a then predicts the heat capacity to within about 1%. More recently, for various oxide glasses from 300 K to T_g , *Inaba et al.* [19.16] have proposed an exponential empirical expression of the form,

$$C_p = 3R \left[1 - \exp \left(-1.5 \frac{T}{T_D} \right) \right], \quad (19.13)$$

where T_D is the Debye temperature. Equation (19.13) predicts a lower C_p than the Debye equation itself at the same temperature for the same T_D . There are also other empirical expressions for C_p (for example, a three-term polynomial in T) that typically involve at least three fitting parameters. *Khalimovskaya-Churkina* and

Fig. 19.4 The specific heat capacity versus As content in As_xSe_{1-x} . (After *Wagner and Kasap* [19.15])

Priven [19.14] have shown that a simple two-parameter empirical expression of the form

$$C_p = a + b \ln T, \quad (19.14)$$

where a and b are composition-dependent parameters, can be fruitfully used to represent the dependence of C_p on T from 100 K to the lower boundary of T_g for various oxide glasses to within about 2.5% error as shown in Fig. 19.3. The authors further show that, to within about 4%,

$$C_p = C_p(293 \text{ K}) [1 + 0.52 \ln(T/293)] . \quad (19.15)$$

What is significant in this equation is that the composition dependence of C_p has been incorporated into $C_p(293 \text{ K})$, and once the latter is calculated, the temperature dependence of C_p is then given by (19.15).

Various empirical rules have been proposed for approximately calculating the heat capacity of oxide glasses from its components. The simplest is the additive rule stated in (19.9), in which the overall heat capacity per mole is found from adding individual molar heat capacities of the constituents, so-called partial molar heat capacities, weighted by their molar fractions. However, for a heterogeneous mixture, that is for a solid in which there are two or more distinct phases present, the specific heat capacity may involve more complicated calculations.

Figure 19.4 shows the heat capacity of an $\text{As}_x\text{Se}_{1-x}$ glass as the composition is varied. The specific heat capacity changes with composition and shows special features at certain critical compositions that correspond to the appearance of various characteristic molecular units in the glass, or the structure becoming optimally connected (when the mean coordination number $\langle r \rangle = 2.4$). With low concentrations of As, the structure is Se-rich and has a floppy structure, and the heat capacity

per mole is about $3R$. As the As concentration is increased, the structure becomes more rigid, and the heat capacity decreases, and eventually at 40 at % As, corresponding to As_2Se_3 , the structure has an optimum connectivity ($\langle r \rangle = 2.4$) and the heat capacity is minimum and, in this case, close to $2.51R$. There appears to be two minima, which probably correspond to $\text{As}_2\text{Se}_{10}$ and As_2Se_5 , that is to AsSe_5 and $\text{AsSe}_{5/2}$ units within the structure.

19.2 Thermal Conductivity

19.2.1 Definition and Typical Values

Heat conduction in materials is generally described by *Fourier's heat conduction law*. Suppose that J_x is the heat flux in the x -direction, defined as the quantity of heat flowing in the x -direction per unit area per unit second: the thermal energy flux. Fourier's law states that the heat flux at a point in a solid is proportional to the temperature gradient at that point and the proportionality constant depends on the material,

$$J_x = -\kappa \frac{dT}{dx}, \quad (19.16)$$

where κ is a constant that depends on the material, called the thermal conductivity (W/m K or $\text{W/m}^\circ\text{C}$), and dT/dx is the temperature gradient. Equation (19.16) is called Fourier's law, and effectively defines the thermal conductivity of a medium. Table 19.2 provides an overview of typical values for the thermal conductivity of various classes of materials.

The thermal conductivity depends on how the atoms in the solid transfer the energy from the hot region to the cold region. In metals, the energy transfer involves the conduction electrons. In nonmetals, the energy transfer involves lattice vibrations, that is atomic vibrations of the crystal, which are described in terms of phonons.

The thermal conductivity, in general, depends on the temperature. Different classes of materials exhibit different κ values and dependence of κ on T , but we can generalize very roughly as follows:

Most pure metals: $\kappa \approx 50\text{--}400 \text{ W/m K}$. At sufficiently high T , e.g. above $\approx 100 \text{ K}$ for copper, $\kappa \approx \text{constant}$. In magnetic materials such as iron and nickel, κ decreases with T .

Most metal alloys: κ lower than for pure metals; $\kappa \approx 10\text{--}100 \text{ W/m K}$. κ increases with increasing T .

Most ceramics: Large range of κ , typically $10\text{--}200 \text{ W/m K}$ with diamond and beryllia being exceptions with high κ . At high T , typically above $\approx 100 \text{ K}$, κ decreases with increasing T .

Most glasses: Small κ , typically less than $\approx 5 \text{ W/m K}$ and increases with increasing T . Typical examples are borosilicate glasses, window glass, soda-lime glasses, fused silica etc. Fused silica is noncrystalline SiO_2 with $\kappa \approx 2 \text{ W/m K}$.

Most polymers: κ is very small and typically less than 2 W/m K and increases with increasing T . Good thermal insulators.

19.2.2 Thermal Conductivity of Crystalline Insulators

In nonmetals heat transfer involves lattice vibrations, that is phonons. The heat absorbed in the hot region increases the amplitudes of the lattice vibrations which is the same as generating more phonons. These new phonons travel towards the cold regions and thereby transport the lattice energy from the hot to cold region. The thermal conductivity κ measures the rate at which heat can be transported through a medium per unit area per unit temperature gradient. It is proportional to the rate at which a medium can absorb energy, that is, κ is proportional to the heat capacity. κ is also proportional to the rate at which phonons are transported which is determined by their mean velocity v_{ph} . In addition, of

Table 19.2 Typical thermal conductivities of various classes of materials at 25 °C

Pure metals	Nb	Sn	Fe	Zn	W	Al	Cu	Ag
κ (W/m K)	53	64	80	116	173	237	400	420

Ceramics and glasses	Glass-borosilicate	Silica-fused (SiO ₂)	S ₃ N ₄	Alumina (Al ₂ O ₃)	Magnesia (MgO)	Sapphire (Al ₂ O ₃)	Beryllia (BeO)	Diamond
κ (W/m K)	0.75	1.5	20	30	37	37	260	1000
Polymers	Poly-propylene	Polystyrene	PVC	Poly-carbonate	Nylon 6,6	Teflon	Polyethylene low density	Polyethylene high density
κ (W/m K)	0.12	0.13	0.17	0.22	0.24	0.25	0.3	0.5

course, κ is proportional to the mean free path Λ_{ph} that a phonon has to travel before losing its momentum, just as the electrical conductivity is proportional to the electron’s mean free path. A rigorous classical treatment gives κ as,

$$\kappa = \frac{1}{3} C_v v_{ph} \Lambda_{ph} , \tag{19.17}$$

where C_v is the heat capacity per unit volume. The mean phonon velocity v_{ph} is constant and approximately independent of temperature so that κ is governed primarily by C_v and Λ_{ph} . The mean free path Λ_{ph} depends on various processes that can scatter the phonons and hinder their propagation along the direction of heat flow. Phonons can collide with other phonons, crystal defects, impurities and crystal surfaces.

At high temperatures, κ is controlled by phonon–phonon scattering. The phonon–phonon collisions that are normally responsible for limiting the thermal conductivity, that is scattering the phonon momentum in the opposite direction to the heat flow, are due to the anharmonicity (asymmetry) of the interatomic potential

Fig. 19.5 Phonons generated in the hot region travel towards the cold region and thereby transport heat energy. Phonon–phonon anharmonic interaction generates a new phonon whose momentum is towards the hot region. (After [19.5])

energy curve. Stated differently, the net force F acting on an atom is not simply βx (where β is a spring constant) but also has an x^2 term, i.e., it is nonlinear. The greater the asymmetry or nonlinearity, the larger is the effect of such momentum-flipping collisions. The same asymmetry that is responsible for thermal expansion of solids is also responsible for determining the thermal conductivity. When two phonons 1 and 2 interact in a crystal region as in Fig. 19.5, the nonlinear behavior and the periodicity of the lattice, cause a new phonon 3 to be generated. This new phonon 3 has the same energy as the sum of 1 and 2 but it is traveling in the wrong direction. (The frequency of 3 is the sum of frequencies of 1 and 2.) The flipping of the phonon momentum is called an *Umklapp process* and is a result of the anharmonicity in the interatomic bond. Figure 19.6 shows the dependence of κ on T for three semiconductors. We can identify three types of behavior.

Fig. 19.6 Thermal conductivity of Si, Ge and GaAs. GaAs for two different levels of doping. Data extracted and replotted: Si [19.17]; Ge [19.18]; GaAs [19.19]

At low temperatures there are two factors that control κ . The phonon concentration is too low for phonon–phonon collisions to be significant. Instead, the mean free path Λ_{ph} is determined by phonon collisions with crystal imperfections, most significantly, crystal surfaces and grain boundaries. Thus, Λ_{ph} depends on the sample geometry and crystallinity. Further, as we expect from the Debye model, C_v depends on T^3 so that κ has the same temperature dependence as C_v , that is $\kappa \propto T^3$. Figure 19.6 shows the dependence of κ on T for Ge, Si and GaAs. Notice that κ increases with increasing T at low temperatures, and that κ also depends on the concentration of dopants (GaAs) or impurities in the crystal, which can scatter phonons. An extensive treatise on the thermal conductivity of semiconductors is given by Bhandari and Rowe [19.20]

As the temperature increases, the temperature dependence of κ becomes controlled by Λ_{ph} rather than C_v , which changes only slowly with T . The mean free path becomes limited by phonon–phonon collisions that obey the Umklapp process. These phonons have energies $\approx \frac{1}{2}k_B T_D$. The concentration of such phonons is therefore proportional to $\exp(T_D/2T)$. Since Λ_{ph} is inversely proportional to the Umklapp-obeying phonon concentration, κ decreases with increasing temperature, following a $\kappa \propto \exp(T_D/2T)$ type of behavior. At temperatures above the Debye temperature, C_v is, of course, constant, and the phonon concentration n_{ph} increases with temperature, $n_{\text{ph}} \propto T$. Thus, the mean free path decreases as $\Lambda_{\text{ph}} \propto 1/T$, which means that $\kappa \propto T^{-1}$, as observed for most crystals at sufficiently high temperatures. Figure 19.7 illustrates the expected dependence of κ on T for nonmetals, with three temperature regimes:

$$\kappa \propto \begin{cases} T^3; & \text{Low } T \\ \exp(-T_D/2T); & \text{Intermediate } T \\ T^{-1}; & \text{High } T. \end{cases} \quad (19.18)$$

Most crystalline semiconductors tend to follow this type of behavior. The thermal conductivity of important semiconductors has been discussed by Adachi [19.3]. In the temperature range above the peak of κ with T , Adachi used a $\kappa = AT^n$ type of power law to model the κ – T data, and has provided an extensive table for A and n for various group IV, III–V and II–V semiconductors [19.3]. For example, for GaAs, over $150 \leq T \leq 1500$, $A = 750$ and $n = -1.28$ so that $\kappa (\text{W/cm K}) = (750)T^{-1.28}$, where T is in Kelvin. Further, Adachi has been able to correlate κ with the lattice parameter a , mean atomic mass \bar{M} in the unit cell and the Debye temperature T_D .

Fig. 19.7 Lattice thermal conductivity versus temperature (K) on a log–log plot. κ is due to phonons

19.2.3 Thermal Conductivity of Noncrystalline Insulators

Glasses

The thermal conductivity of glasses tends to be substantially smaller than their crystalline counterparts, and tends to increase with the temperature almost monotonically. The most striking difference at room temperature is that, as the temperature is decreased, κ for a glass decreases whereas for a crystal it increases. This dif-

Fig. 19.8 The temperature dependence of κ for four types of glasses. Data in Figure 2 of Zeller and Pohl [19.21] replotted

ference has been qualitatively attributed to the phonon mean free path Λ_{ph} in a glass remaining roughly constant as the temperature is lowered and being limited by the range of disorder in the structure, which is a few atomic spacings [19.22, 23]. While intuitively this explanation seems reasonable, a more rigorous derivation excludes (19.17) since concepts like phonon velocity and wavelength tend to become meaningless over very short distances [19.24]. Most of the theories that have been proposed for describing κ more rigorously in the non-crystalline state are quite mathematical, and beyond the scope of this review based on materials science. (These models include the Kubo transport equation [19.25], hopping of localized vibrations [19.26], simulations based on molecular dynamics [19.27] etc.) Figure 19.8 shows κ versus T for a few selected glasses [19.21, 28]. Other glasses tend to follow this type of behavior in which there are three regions of distinct behavior. At very low temperatures (I in Fig. 19.8, below 1–2 K, $\kappa \approx T^n$ where $n = 1.8\text{--}2.0$). In the intermediate temperature regime, from about 2 K to about 20–30 K, κ exhibits a plateau. At high temperatures, above 20–30 K, beyond the plateau, κ increases with T , with a decreasing slope.

Polymers

Crystalline polymers tend to follow the general predictions in Fig. 19.7 that at high temperatures κ decreases with the temperature. As the degree of crystallinity decreases, κ also decreases, and eventually for amorphous polymers κ is substantially smaller than the crystalline phase, and κ increases with increasing temperature. If ρ_c and ρ_a are the densities of a given polymer in the crystalline (c) and amorphous (a) phase, then various empirical rules have been proposed to relate the conductivities of c- and a-phases through the ratio ρ_c/ρ_a of their densities. For example, in one empirical rule [19.29] $\kappa_c/\kappa_a = 1 + 1.58[(\rho_c/\rho_a) - 1]$. This means that, if we know κ_c , and ρ_c/ρ_a , we can calculate κ_a . If we know the density ρ of the partially crystalline polymer or the volume fraction v_a of the amorphous phase, then we can use an appropriate mixture rule to find the overall κ . (A solved problem is given as an example in chapter 17 of [19.10].) Figure 19.9 shows the dependence of κ on T for three different degrees of crystallinity in the structure; clearly κ versus T is strongly influenced by the crystallinity of the structure.

Figure 19.10 shows the temperature dependence of κ when it has been normalized to its value $\kappa(T_g)$ at the glass-transition temperature T_g against the normalized temperature, T/T_g for a number of amorphous

polymers. While there are marked differences between various polymers, there is nonetheless an overall trend in which κ increases up to T_g and thereafter decreases with T . The solid curve in Fig. 19.10 indicates an overall trend. Notice how similar the κ values are.

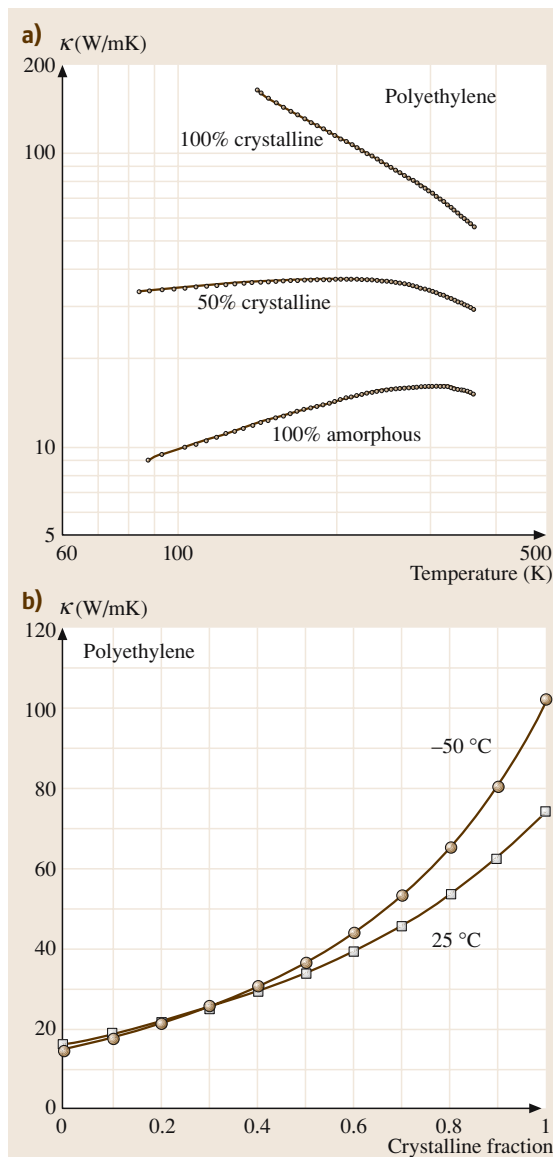

Fig. 19.9 (a) κ – T behavior for polyethylene for a fully crystalline, fully amorphous and 50% crystalline structures. (b) Dependence of κ on the crystallinity of polyethylene. Data extracted and replotted from [19.29]

Fig. 19.10 Normalized thermal conductivity, $\kappa(T)/\kappa(T_g)$ versus normalized temperature, T/T_g , for various polymers. (Figure 17.2 in [19.10])

The overall or effective thermal conductivity of polymer blends can be usually estimated from the individual conductivities, the volume or weight fractions of the constituents, and the crystallinity of the structure; the problem can be quite complicated. A good example in which κ has been examined for a polymer blend as a function of blend composition has been given by Agari et al. [19.30], who also test various mixture rules.

The thermal conductivity of polymeric composite materials (as opposed to blends) can be estimated from various mixture rules [19.31, 32]. For example, if a matrix with κ_1 contains spherical particles with κ_2 , then the composite has a thermal conductivity,

$$\kappa = \kappa_1 \frac{2\kappa_1 + \kappa_2 - 2v_2(\kappa_1 - \kappa_2)}{2\kappa_1 + \kappa_2 + v_2(\kappa_1 - \kappa_2)}, \quad (19.19)$$

where v_2 is the volume fraction of the particles (with κ_2).

19.2.4 Thermal Conductivity of Metals

Although the heat capacity of metals is due the lattice vibrations, the thermal conductivity is due to the free conduction electrons. Both charge transport and heat transport are carried by the conduction electrons, and hence the electrical and thermal conductivity, σ and κ respectively, are related. Normally only electrons around

the Fermi level contribute to conduction and energy transport. In general κ and σ can be written as

$$\kappa = \frac{1}{3} C_e v_F \ell_e \quad \text{and} \quad \sigma = \frac{1}{3} e^2 v_F \ell_e g(E_F), \quad (19.20)$$

where C_e is the electronic heat capacity per unit volume, v_F is the Fermi velocity, $g(E_F)$ is the density of states at E_F (Fermi level), and ℓ_e is the electron mean free path. The scattering of electrons limits ℓ_e , which then limits κ and σ . If we then apply the free-electron theory to substitute for C_e and $g(E_F)$ then the ratio of κ to σT turns out to be a constant, which depends only on the constants k and e ; ℓ_e cancels out in this ratio. A proper derivation involves solving the Boltzmann transport equation in the presence of a temperature gradient [19.33], and leads to the well-known *Wiedemann–Franz–Lorenz* (WFL) law

$$\frac{\kappa}{\sigma T} = C_{\text{WFL}} = \frac{\pi^2 k^2}{3e^2} = 2.44 \times 10^{-8} \text{ W } \Omega / \text{K}^2, \quad (19.21)$$

where C_{WFL} is called the *Lorentz number*.

As shown in Fig. 19.11, the WFL law is well obeyed at room temperature for most pure metals and their alloys. The WFL law is normally well obeyed over a wide

Fig. 19.11 Thermal conductivity versus electrical conductivity for various metals (both pure metals and alloys) at 20 °C. (From [19.5])

temperature range, and also by many liquid pure metals. Consequently the thermal conductivity κ of a metal or an alloy can be readily calculated given the conductivity or resistivity ρ . For example, we can easily calculate the resistivity of a solid solution alloy by using Matthiessen's and Nordheim's rules (as explained in this handbook by Koughia et al. in Chapt. 2) and then simply calculate κ from (19.21). Figure 19.12 shows the typical dependence of κ on T for two pure metals (Cu and Al) and two alloys (brass and Al-14%Mg). Above the Debye temperature, for pure metals, $\sigma \propto 1/T$, so that the thermal conductivity remains almost constant, as in Fig. 19.12. For alloys, σ values are smaller than the corresponding pure metals and σ exhibits a weaker temperature depen-

Fig. 19.12 Thermal conductivity versus temperature for two pure metals (Cu and Al) and two alloys (brass and Al-14% Mg). (From [19.5])

dence. Consequently κ is smaller and increases with the temperature, as shown in Fig. 19.12.

While for pure metals and many alloys κ is due to the conduction electrons, the phonon contribution can nonetheless become comparable to the electron contribution for those alloys that have substantial resistivity or at low temperatures. Glassy metals (or metallic glasses) usually have two or more elements alloyed; one of the elements is usually a nonmetal or a metalloid. Their resistivities tend to be higher than usual crystalline or polycrystalline alloys. Both conduction electrons and also phonons contribute to the thermal conductivity of these glassy metals. For example, for $\text{Fe}_{80}\text{B}_{20}$, $\rho = 1220 \text{ n}\Omega \text{ m}$ (compare with $17 \text{ n}\Omega \text{ m}$ for Cu), and the phonon contribution is about 15% at 273 K and 61% at 100 K [19.34].

19.3 Thermal Expansion

19.3.1 Grüneisen's Law and Anharmonicity

Nearly all materials expand as the temperature increases. The thermal coefficient of linear expansion, or simply, the thermal expansion coefficient α is defined as the fractional change in length per unit temperature increase, or

$$\alpha = \frac{1}{L_0} \cdot \left(\frac{dL}{dT} \right)_{T_0}, \quad (19.22)$$

where L_0 is the original length of the substance at temperature T_0 , dL/dT is the rate of change of length with temperature at the reference temperature T_0 .

The principle of thermal expansion is illustrated in Fig. 19.13, which is the potential-energy curve $U(r)$ for two atoms separated by a distance r in a crystal. At temperature T_1 , the atoms would be vibrating about their equilibrium positions between B and C ; compressing (B) and stretching (C) the bond between them. The line BC corresponds to the total energy E of the pair

Table 19.3 The Grüneisen parameter for some selected materials with different types of interatomic bonding (FCC = face-centered cubic; BCC = body-centered cubic)

Material	ρ (g/cm ³)	α ($\times 10^{-6}$ K ⁻¹)	K (GPa)	c_s (J/kg K)	γ
Iron (metallic, BCC)	7.9	12.1	170	444	0.20
Copper (metallic, FCC)	8.96	17	140	380	0.23
Germanium (covalent)	5.32	6	77	322	0.09
Glass (covalent-ionic)	2.45	8	70	800	0.10
NaCl (ionic)	2.16	39.5	28	880	0.19
Tellurium (mixed)	6.24	18.2	40	202	0.19
Polystyrene (van der Waals)	1.05	100	3	1200	0.08

of atoms. The average separation at T_1 is at A, halfway between B and C. The PE curve $U(r)$ is asymmetric, and it is this asymmetry that leads to the phenomenon of thermal expansion. When the temperature increases from T_1 to T_2 the atoms vibrate between B' and C' and the average separation between the atoms also increases, from A to A', which is identified as thermal expansion. If the PE curve were symmetric, then there would be no thermal expansion. The extent of expansion (A to A') depends on the amount of increase from BC to B'C' per degree of increase in the temperature. α must therefore also depend on the heat capacity. When the temperature increases by a small amount δT , the energy per atom increases by $(C_v \delta T)/N$, where C_v is the heat capacity per unit volume and N is the number of atoms per unit volume. If $C_v \delta T$ is large then the line B'C' in Fig. 19.13 will be higher up on the energy curve and the average separation A' will therefore be larger. Thus, $\alpha \propto C_v$. Further, the average separation, point A, depends on how much the bonds are stretched and compressed. For large amounts of displacement from equilibrium, the average A will be greater as more asymmetry of the PE curve is used. Thus, smaller is the elastic modulus K , the greater is α ; clearly $\alpha \propto C_v/K$.

If we were to expand $U(r)$ about its minimum value U_{\min} at $r = r_0$, we would obtain the Taylor expansion to the cubic term as,

$$U(r) = U_{\min} + (1/2)\beta(r - r_0)^2 - (1/3)g(r - r_0)^3, \quad (19.23)$$

where β and g are coefficients related to second and third derivatives of U at r_0 . The term $(r - r_0)$ is missing because we are expanding a series about U_{\min} where $dU/dr = 0$. The U_{\min} and the $\beta_2(r - r_0)^2$ term give a parabola about U_{\min} which is a symmetric curve around r_0 and therefore does not lead to thermal expansion. It is the cubic term that gives the expansion because it leads to asymmetry. Thus, the amount of expansion α

**Fig. 19.13** Interatomic potential energy (PE) U curve, which has a minimum when the atoms in the solid attain the interatomic separation at $r = r_0$

also depends on the amount of asymmetry with respect to symmetry that is β/g . Thus, α is proportional to both C_v/K and g/β . The third term in (19.23) is called *anharmonicity* in the interatomic PE curve. The ratio of g to β depends on the nature of the bond. A simplified analytical treatment [19.35] gives α as,

$$\alpha \approx 3\gamma \frac{C_v}{K}; \quad \gamma = \frac{r_0 g}{3\beta}, \quad (19.24)$$

where γ is a constant called the *Grüneisen parameter*, which represents the relative asymmetry of the energy curve, g/β . γ is of the order of unity for many materials; experimentally, $\gamma = 0.1$ – 1 . We can also write the Grüneisen law in terms of the molar heat capacity C_m [heat capacity per mole or the specific heat capacity c_s (heat capacity per unit mass)]. If ρ is the density, and M_{at} is the atomic mass of the constituent atoms of the crystal, then

$$\lambda = 3\gamma \frac{\rho C_m}{M_{\text{at}} K} = 3\gamma \frac{\rho c_s}{K}. \quad (19.25)$$

Given the experimental values for α , K , ρ and c_s , the Grüneisen parameters have been calculated from (19.25)

and are listed in Table 19.3. An interesting feature is that the experimental γ values, within a factor of 2–3, are about the same, at least to an order of magnitude. Equation (19.24) also indicates that the dependence of α on T should resemble the dependence of C_v on T , which is borne out by experiments.

19.3.2 Thermal Expansion Coefficient α

The thermal expansion coefficient normally depends on the temperature, $\alpha = \alpha(T)$, and typically increases with increasing temperature, except at the lowest temperatures. Figure 19.14 shows α versus T for selected materials and also compares α for a wide range of materials at 300 K. In very general terms, except at very low (typically below 100 K) and very high temperatures (near the melting temperature), for most metals α does not depend strongly on the temperature; many engineers take α for a metal to be approximately temperature independent. Further, higher-melting-point temperature metals tend to have lower α .

To calculate the final length L from the original length L_0 that corresponds to the temperature increasing from T_0 to T , we have to integrate $\alpha(T)$ with respect to temperature from T_0 to T . If $\bar{\alpha}$ is the mean value for the expansion coefficient from T_0 to T , then

$$L = L_0[1 + \bar{\alpha}(T - T_0)] \text{ and} \quad (19.26)$$

$$\bar{\alpha} = \frac{1}{(T - T_0)} \int_{T_0}^T \alpha(T) dT \quad (19.27)$$

For example, the expansion coefficient of silicon over the temperature range 120–1500 K is given by [19.36]

Fig. 19.14 α versus T for selected materials and comparison of α for a range of materials at 300 K. (After [19.5])

as

$$\alpha = 3.725 \times 10^{-6} \left(1 - e^{-5.88 \times 10^{-3}(T-124)} \right) + 5.548 \times 10^{-10} T, \quad (19.28)$$

where T is in Kelvin. At 20 °C, $\alpha = 2.51 \times 10^{-6} \text{ K}^{-1}$, whereas from 20 °C to 320 °C, $\bar{\alpha} = 3.35 \times 10^{-6} \text{ K}^{-1}$. Most $\alpha(T)$ expressions have exponential-type expressions as in (19.28) but they can always be expanded in terms of T or $(T - T_0)$ up to the third term, beyond which errors become insignificant.

19.4 Enthalpic Thermal Properties

19.4.1 Enthalpy, Heat Capacity and Physical Transformations

Consider the behavior of the enthalpy $H(T)$ versus temperature T of a typical material as it is cooled from a liquid state starting at O as shown in Fig. 19.15 (the sketch is idealized to highlight the fundamentals). For crystalline solids, at the melting or fusion temperature T_m , the liquid L solidifies to form a crystalline solid C . Some degree of undercooling is necessary to nucleate the crystals but we have ignored this fact

in Fig. 19.15 so that T_m is the thermodynamic melting temperature where the Gibbs free energies of the liquid (L) and the crystal (C) are the same. The heat capacity $C_{\text{liquid}} = dH_{\text{liquid}}/dT$ for the liquid is greater than that for the crystal, $C_{\text{crystal}} = dH_{\text{crystal}}/dT$, as apparent from the H - T slopes in Fig. 19.15. The fusion enthalpy ΔH_f corresponds to the enthalpy change between the liquid and crystalline phases, L and C , in Fig. 19.15.

When a glass-forming liquid is cooled, it does not crystallize at T_m ; its crystallization kinetics are too slow or negligible. Its enthalpy H continues to decrease along

Fig. 19.15 Enthalpy H versus temperature T

the liquid H versus T line with a slope C_{liquid} and it becomes a supercooled liquid. However, as the cooling proceeds, eventually, over a certain small temperature range around a temperature marked as T_g in Fig. 19.15, the atomic motions become too sluggish, and the viscosity becomes too high to follow the liquid-like behavior. The material cools along a solid-like H - T curve that is almost parallel to the crystalline or solid H - T line. This region where the slope or the heat capacity is similar to that of the solid or the crystal (C_{crystal}) is called the glassy state. The intersection of the liquid-like (supercooled) and solid-like (glass) H - T lines defines a *glass-transition temperature* T_g as observed under cooling at a particular cooling rate q . T_g depends on the cooling rate, and obviously on the structure. C_p changes in a step-like fashion over a small interval around T_g during cooling as shown in Fig. 19.15. The shift in T_g with q can provide valuable information on the kinetics of the glass-transformation process as discussed below. The glass enthalpy is greater than the crystalline enthalpy due to the disorder in the glass structure.

Suppose we stop the cooling at an ambient temperature T_a , corresponding to the glass state G . The glass enthalpy $H_{\text{glass}}(T_a)$ will relax via structural relaxations toward the enthalpy of the metastable liquid-like equilibrium state $H_{\text{liquid}}(T_a)$ at L' . This process is called aging or annealing. When we start heating a glass, its initial enthalpy can be anywhere between G and L' , depending on the thermal history (including aging) and the cooling rate.

When the sample at $H(T_a)$ at G' is heated at a constant rate r , as shown in Fig. 19.16, the enthalpy of

Fig. 19.16 Isothermal aging at T_a changes the glass enthalpy. When the glass is heated at a constant rate r , it undergoes glass transition at around T_g , and then ideally crystallization and then melting

the system, as a result of long structural relaxation times at these low temperatures, follows the glass H - T curve until the structural relaxation rate is sufficiently rapid to allow the system to recover toward equilibrium $H_{\text{liquid}}(T)$; the transition is from G'' to L'' . The sigmoidal-like change in $H(T)$ leads to the glass-transformation endotherm observed for many glasses when they are heated through T_g . This endothermic heat, called the enthalpy of relaxation, depends on the duration of aging, and the structural relaxation processes, which in turn depend on the structure (e.g. [19.37]). The observed glass-transition temperature T_g during heating depends not only on the heating rate r but also on the initial state $H(T_a)$ or G' . On the other hand, during cooling from the melt down to low temperatures, one observes only a change in the heat capacity. As we further heat the sample, the supercooled liquid state can crystallize, from L''' to C'' and form a true solid, usually polycrystalline. This transformation from L''' to C'' releases heat; it is exothermic. At T_m , the solid melts to form the liquid, C changes to L , which means that heat is absorbed.

It is apparent from the simple H - T behavior in Fig. 19.16 that there are at least several key parameters of interest in characterizing the thermal properties of materials: the heat capacity of the liquid, crystal and glass phases, C_{liquid} , C_{crystal} , C_{glass} , their temperature dependences, melting or fusion temperature T_m , fusion enthalpy ΔH_f , crystallization onset temperature (L'''),

exothermic enthalpy of crystallization ($L''' - C'''$), T_g (which depends on various factors), and the endothermic glass-transformation enthalpy ($L'' - G''$). These properties are most conveniently examined using a *differential scanning calorimeter* (DSC).

19.4.2 Conventional Differential Scanning Calorimetry (DSC)

Principles

Differential scanning calorimetry (DSC) is a method which is extensively used to measure heats and temperatures of various transitions and has been recognized as a very useful tool for the interpretation of thermal events as discussed and reviewed by a number of authors (see for example [19.38–44]). In essence, the DSC measures the net rate of heat flow $Q' = dQ/dT$, into a sample with respect to heat flow into a reference inert sample, as the sample temperature is ramped. Figure 19.17 shows a simplified schematic diagram of the heat-flux DSC cell. The constantan disk allows heat transfer to and from the reference and sample pans by thermal conduction. Due to symmetry, the thermal resistance of the heat paths from the heater to the reference and sample pans is approximately the same. The constantan disk has two slightly raised platforms on which the reference and sample pans are placed. Chromel disks fixed under these platforms form area thermocouple junctions with the constantan platforms. The constantan-chromel thermocouples are in series and read the temperature difference ΔT between the reference and sample pans. There are also alumel–chromel thermocouples attached to the chromel disks to measure the individual reference and sample temperatures.

The measured temperature difference ΔT corresponds to a differential heat flow $Q' = dQ/dt$ between the sample and the reference pans by virtue of Fourier's

Fig. 19.17 Schematic illustration of heat-flux DSC cell. R and S refer to reference and sample pans

law of heat conduction,

$$Q' = \Delta T/R, \quad (19.29)$$

where R is the effective thermal resistance of the heat flow path to the sample (or reference) through the constantan disk. In conventional thermal analysis, the sample temperature is either ramped linearly at a constant heating or cooling rate or kept constant (as in isothermal experiments).

A typical example of a conventional DSC is shown in Fig. 19.18 where the thermogram evinces three distinct regions that correspond to the glass transition (T_g), crystallization and melting. T_g in DSC analysis is normally defined in terms of an onset temperature as in Fig. 19.18. The crystallization exotherm is normally used to obtain a crystallization onset temperature T_c and a peak crystallization rate temperature T_p that corresponds to the location of the peak crystallization. ΔH_c and fusion ΔH_f enthalpies are obtained by integrating the corresponding peaks as shown in Fig. 19.18 with an appropriate baseline. The base line represents the overall heat capacity of the sample, which changes during the transformation since the sample is gradually transformed into the new phase. Usually a simple sigmoidal, or even a straight line between the onset and the end points, is sufficient for an accurate determination of the enthalpy.

Conventional DSC has been used to study and characterize a wide range of physical and chemical transformations. When the DSC is used in a heating or cooling scan, the temperature of the sample is ramped along

Fig. 19.18 Typical DSC signal for a chalcogenide $\text{Se}_{0.936}\text{Te}_{0.064}$ glass sample (well relaxed or aged). From left to right: the glass transition, crystallization and the melting temperatures and corresponding enthalpies of transitions for this material. $\Delta H_c = \Delta H_{\text{crystallization}}$; $\Delta H_f = \Delta H_{\text{fusion}}$

$T = T_0 + rt$, where T_0 is the initial temperature. Consequently, the transformations in DSC are carried out under non-isothermal conditions, and well-known isothermal rate equations cannot be directly applied without some modification.

Glass Transformation

There are extensive discussions in the literature on the meaning of the glass-transition region and the corresponding T_g (e.g. [19.45–50]). The most popular interpretation of T_g is based on the fact that this transformation is a kinetic phenomenon. The glass-transformation kinetics have been most widely studied by examining the shift in T_g with the heating or cooling rate in a so-called T_g -shift technique. The relaxation process can be modeled by assuming that the glass structure has a characteristic structural relaxation time that controls the rate at which the enthalpy can change. It is well recognized that the glass-transformation kinetics of glasses are nonlinear. In the simplest description, the relaxation can be conveniently described by using a single phenomenological relaxation time τ (called the Narayanaswamy or Tool–Narayanaswamy–Moynihan relaxation time) that depends not only on the temperature but also on the glass structure through the fictive temperature T_f as

$$\tau(T, T_f) = \tau_0 \exp[x\Delta h^*/RT + (1-x)\Delta h^*/RT_f], \quad (19.30)$$

where Δh^* is the activation enthalpy, T_f is the fictive temperature and x is the partition parameter which determines the relative contributions of temperature and structure to the relaxation process. T_f is defined in Fig. 19.16 as the intersection of the glass line passing through the starting enthalpic state G' and the extended liquid H – T lines. It depends on the starting enthalpy G' so that T_f is used as a convenient temperature parameter to identify the initial state at G' . Due to the presence of the structural parameter x , the activation energies obtained by examining the heating and cooling rate dependences of the glass-transition temperature are not the same. If the shift in T_g is examined as a function of the cooling rate q starting from a liquid-like state (above T_g) then a plot of $\ln q$ versus $1/T_g$ (called a *Ritland plot* [19.51]) should yield the activation enthalpy Δh^* in (19.30) [19.52–54]. In many material systems, the relaxation time τ in (19.30) is proportional to the viscosity, $\tau \propto \eta$ [19.55–57] so that Δh^* from cooling scans agrees with the activation energy for the viscosity [19.58–62] over the same temperature range. The viscosity η usually

follows either an Arrhenius temperature dependence, as in oxide glasses, or a Vogel–Tammann–Fulcher behavior, $\eta \propto \exp[A/(T - T_0)]$, where A and T_0 are constants, as in many polymers and some glasses, e.g. chalcogenides.

The relaxation kinetics of various structural properties such as the enthalpy, specific volume, elastic modulus, dielectric constant etc. have been extensively studied near and around T_g , and there are various reviews on the topic (e.g. [19.63]). One particular relaxation kinetics that has found widespread use is the stretched exponential in which the rate of relaxation of the measured property is given by

$$\text{Rate of relaxation} \propto \exp\left[-\left(\frac{t}{\tau}\right)^\beta\right], \quad (19.31)$$

where β (< 1) is a constant that characterizes the departure from the pure exponential relaxation rate. Equation (19.31) is often referred to as the *Kohlrausch–Williams–Watts* (KWW) [19.64] stretch exponential relaxation function. β depends not only on the material but also on the property that is being studied. In some relaxation processes, the whole relaxation process over a very long time is sometimes described by two stretched exponentials to handle the different fast and slow kinetic processes that take place in the structure [19.65].

The kinetic interpretation of T_g implies that, as the cooling rate is slowed, the transition at T_g from the supercooled liquid to the glass state is observed at lower temperatures. There is however a theoretical thermodynamic boundary to the lowest value of T_g . As the supercooled liquid is cooled, its entropy decreases faster than that of the corresponding crystal because $C_{\text{liquid}} > C_{\text{crystal}}$. Eventually at a certain temperature T_0 , the relative entropy lost $\Delta S_{\text{liquid-crystal}}$ by the supercooled liquid with respect to the crystal will be the same as the entropy decrease (latent entropy of fusion) $\Delta S_f = \Delta H_f/T_m$ during fusion. This is called *Kauzmann's paradox* [19.66], and the temperature at which $\Delta S_{\text{liquid-crystal}} = \Delta S_f$ is the lowest theoretical boundary for the glass transformation; $T_g > T_0$.

The changes in T_g with practically usable heating or cooling rates are usually of the order of 10 °C or so. There have been various empirical rules that relate T_g to the melting temperature T_m and the glass structure and composition. Since T_g depends on the heating or cooling rate, such rules should be used as an approximation; nonetheless, they are extremely useful in engineering as a guide to the selection and use of materials.

Table 19.4 Some selected examples of T_g dependences on various factors

Rule	Notation	Comment
$T_g \approx (2/3)T_m$	T_g and T_m in K. T_m = melting temperature of corresponding crystalline phase.	Kauzmann's empirical rule [19.66]. Most glass structures including many amorphous polymers [19.67]. Some highly symmetrical polymers with short repeat units follow $T_g \approx (1/2)T_m$ [19.10]
$\ln(q) \approx -\Delta h^*/RT_g + C$	q = cooling rate; Δh^* = activation energy in (19.30); C = constant.	Dependence of T_g on the cooling rate. Δh^* may depend on the range of temperature accessed. Bartenev–Lukianov equation [19.51, 68]
$T_g \approx T_g(\infty) + C/M_n$	M_n = average molecular weight of polymer; C = constant; $T_g(\infty)$ is T_g for very large M_n	Dependence of T_g on the average molecular weight of a polymer [19.69, 70]. Tanaka's rule
$\ln(T_g) \approx 1.6Z + C$	Z = mean coordination number, C = constant (≈ 2.3)	Network glasses. Dependence of T_g on the mean coordination number. Neglects the heating rate dependence. [19.71]
$T_g(x) = T_g(0) - 626x$	T_g in K; x is atomic fraction in $a: (\text{Na}_2\text{O} + \text{MgO})_x(\text{Al}_2\text{O}_3 + \text{SiO}_2)_{1-x}$ $b: (\text{PbO})_x(\text{SiO}_2)_{1-x}$ $c: (\text{Na}_2\text{O})_x(\text{SiO}_2)_{1-x}$ $T_g(0) = 1080 \text{ K for } a;$ $967 \text{ K for } b; 895 \text{ K for } c.$	$\pm 5\%$. Silicate glasses [19.72]; x is network modifier. $0.01 < x < 0.6$

Non-Isothermal Phase Transformations

The crystallization process observed during a DSC heating scan is a non-isothermal transformation in which nucleation and growth occur either at the same time as in homogenous nucleation or nucleation occurs before growth as in heterogenous nucleation. In the case of isothermal transformations by nucleation and growth, the key equation is the so-called *Johnson–Mehl–Avrami equation*,

$$x = 1 - \exp(-Kt^n), \quad (19.32)$$

where $K \propto \exp(-E_A/k_B T)$ is the thermally activated rate constant, and n is a constant called the *Avrami index* whose value depends on whether the nucleation is heterogeneous or homogenous, and the dimensionality m of growth ($m = 1, 2$ or 3 for one-, two- or three-dimensional growth). For example, for growth from preexisting nuclei (heterogeneous nucleation) $n = m$, and for continuing nucleation during growth, $n = m + 1$. A detailed summary of possible n and m values has been given by Donald [19.73]

DSC studies however are conventionally non-isothermal. There have been numerous papers and discussions on how to extract the kinetic parameters of the transformation from a DSC non-isothermal experiment [19.74–78]. It is possible to carry out a reasonable examination of the crystallization kinetics by combining a single scan experiment with a set of multiple scans; there are many examples in the literature (e.g. [19.78, 79]). Suppose that we take a single DSC

scan, as in Fig. 19.18, and calculate the fraction of crystallized material x at a temperature T . The plot of $\ln[-\ln(1-x)]$ versus $1/T$ (*Coats–Redfern–Sestak plot* [19.80, 81]) then provides an activation energy E'_A from a single scan. For heterogenous nucleation, E'_A is mE_G , whereas for homogenous nucleation it is $E_N + mE_G$, where E_G is the activation energy for growth and E_N is the activation energy for nucleation. Clearly, we need to know something about the nucleation process and dimensionality of growth to make a sensible use of E'_A . Thus,

$$\ln[-\ln(1-x)] = -\frac{E'_A}{RT} + C', \quad (19.33)$$

where C' is a constant.

Suppose we then examine how the peak rate temperature T_p shifts with the heating rate r . Then a plot of $\ln(r/T_p^2)$ versus $1/T_p$ is called a *Kissinger plot* [19.82, 83], and gives an activation energy E''_A . Thus,

$$\ln\left(\frac{r}{T_p^2}\right) = -\frac{E''_A}{RT_p} + C'', \quad (19.34)$$

where C'' is a constant. In heterogenous nucleation E''_A simply represents the activation energy of growth E_G , whereas if the nucleation continues during growth, $E''_A = (E_N + mE_G)/(m+1)$. The ratio E'_A/E''_A represents the non-isothermal Avrami index n . Table 19.5 provides an overview of various thermal analysis techniques that have been used for characterizing non-isothermal phase transformations.

Table 19.5 Typical examples of studies of transformation kinetics. Usual interpretation of E'_A and E''_A are $E'_A = mE_G$ or $(E_N + mE_G)$ and $E''_A = E_G$ or $(E_N + mE_G)/(m + 1)$; \dot{x} is the rate of crystallization

Study	Method and plot	Slope provides	Method
Single scan	$\ln[-\ln(1-x)]$ versus $1/T$	E'_A	<i>Coats-Redfern-Sestak</i> [19.80,81]
Single scan	$\frac{\dot{x}}{(1-x)[-\ln(1-x)]^{(n-1)/n}}$	E''_A	If n chosen correctly, this agrees with the Kissinger method [19.77,79]. Independent of the initial temperature
Multiple scan	$\ln(r/T_p^2)$ versus $1/T_p$	E''_A	<i>Kissinger</i> [19.82,83]. Initial temperature effect in [19.77]
Multiple scan	$\ln(r^n/T_p^2)$ versus $1/T_p$	mE''_A	Modified Kissinger; <i>Matusita, Sakka</i> [19.89,90]
Multiple scan	$\ln r$ versus $1/T_c$	E''_A	<i>Ozawa method</i> [19.74–76]
Multiple scan	$\ln[r/(T_p - T_c)]$ versus $1/T_p$; T_c = initial temperature	E''_A	<i>Augis, Bennett</i> [19.91]
Multiple scan	$[d\Delta H/dt]_{\max}$ versus $1/T_p$; $\dot{x} = [d\Delta H/dt]_{\max}$	E''_A	<i>Borchardt-Pilonyan</i> [19.92,93]
Multiple scan	$\ln(r/T_1^2)$ versus $1/T_1$; when $x = x_1$, $T = T_1$; T_1 depends on r	E''_A	<i>Ozawa-Chen</i> [19.94,95]
Multiple scan	$\ln[-\ln(1-x)]$ versus $\ln r$; x is the crystallized amount at $T = T_1$; T_1 is constant	$-n$	<i>Ozawa method</i> [19.90,94]

DSC has been widely used to study the kinetics of crystallization and various phase transformations occurring in a wide range of material systems; there are numerous recent examples in the literature [19.84–88]. Equations (19.33) and (19.34) represent a simplified analysis. As emphasized recently [19.73], a modified Kissinger analysis [19.89,90] involves plotting $\ln(r^n/T_p^2)$ versus $1/T_p$, the slope of which represents an activation energy, mE''_A ; however, the latter requires

some knowledge of n or m to render the analysis useful. n can be obtained examining the dependence of $\ln[-\ln(1-x)]$ on $\ln r$ at one particular temperature, which is called the Ozawa method as listed in Table 19.5 [19.90]. It is possible to combine the modified Kissinger analysis with an isothermal study of crystallization kinetics to infer n and m given the type of nucleation process (heterogeneous or homogenous) that takes place.

19.5 Temperature-Modulated DSC (TMDSC)

19.5.1 TMDSC Principles

In the early 1990s, a greatly enhanced version of the DSC method called temperature-modulated differential scanning calorimetry (MDSC™) was introduced by the efforts of *Reading* and coworkers [19.96–98]. The MDSC method incorporates not only the ability of conventional DSC but it also provides significant and distinct advantages over traditional DSC. The benefits of the MDSC technique have been documented in several recent papers, and include the following: separation of complex transitions, e.g. glass transition, into easily interpreted components; measurement of heat flow and heat capacity in a single experiment; ability to determine more accurately the initial crystallinity of the studied material; increased sensitivity

for the detection of weak transitions; increased resolution without the loss of sensitivity; measurement of thermal conductivity [19.99,100]. One of the most important benefits is the separation of complex transitions such as the glass transition into more easily interpreted components. Recent applications of MDSC to glasses has shown that it can be very useful for the interpretation of thermal properties, such as the heat capacity, in relation to the structure as, for example, in the case of chalcogenide glasses (e.g. [19.15,101,102]).

The MDSC™ that is currently commercialized by TA Instruments uses a conventional heat-flux DSC cell whose heating block temperature is sinusoidally modulated. In MDSC, the sample temperature is modulated sinusoidally about a constant ramp so that the tempera-

ture T at time t is,

$$T = T_0 + rt + A \sin(\omega t), \quad (19.35)$$

where T_0 is the initial (or starting) temperature, r is the heating rate (which may also be a cooling ramp q), A is the amplitude of the temperature modulation, $\omega = 2\pi/P$ is the angular frequency of modulation and P is the modulation period. It should be emphasized that (19.35) is a simplified statement of the fact that the cell has reached a steady-state operation and that the initial temperature transients have died out. The resulting instantaneous heating rate, dT/dt , therefore varies sinusoidally about the average heating rate r , and is given by

$$dT/dt = r + A\omega \sin(\omega t). \quad (19.36)$$

At any time, the apparatus measures the sample temperature and the amplitude of the instantaneous heat flow (by measuring ΔT) and then, by carrying out a suitable Fourier deconvolution of the measured quantities, it determines two quantities (which have been termed by TA Instruments):

1. Reversing heat flow (RHF),
2. Nonreversing heat flow (NHF).

Fourier transforms are made on one full cycle of temperature variation, which means that the average quantities refer to moving averages. The average heat flow, which corresponds to the average heating rate (r), is called the total heat flow (HF). Total heat flow is the only quantity that is available and hence it is the only quantity that is always measured in conventional DSC experiments. MDSC determines the heat capacity using the magnitudes of heat flow and heating rate obtained by averaging over one full temperature cycle. If triangular brackets are used for averages over one period P , then $\langle Q' \rangle$ is the average heat flow per temperature cycle. The heat capacity per cycle is then calculated from

$$mC_P = \langle \text{Heat flow} \rangle / \langle \text{Heating rate} \rangle, \quad (19.37)$$

where m is the mass of the sample. This C_P has been called the *reversing heat capacity*, though Schawe has defined as the complex heat capacity [19.12]. The reversing in this context refers to a heat flow that is reversing over the time scale of the modulation period. Furthermore, it is assumed that C_P is constant, that is, it does not change with time or temperature over the modulation period. The reversing heat flow is then obtained by

$$\text{RHF} = C_P \langle dT/dt \rangle. \quad (19.38)$$

The nonreversing heat flow (NHF) is the difference between the total heat flow and the reversing heat flow and represents heat flow due to a kinetically hindered process such as crystallization. There are a few subtle issues in the above condensed qualitative explanation. First is that the method requires several temperature cycles during a phase transition to obtain RHF and NHF components, which sets certain requirements on r , A and ω . The second is that the phase difference between the heat flow and the heating rate oscillations is assumed to be small as it would be the case through a glass-transition region or crystallization; but not through a melting process. There are a number of useful discussions and reviews on the MDSC technique and its applications in the literature [19.103–107].

19.5.2 TMDSC Applications

At present there is considerable scientific interest in applying TMDSC measurements to the study of glass-transformation kinetics in glasses and polymers (e.g. [19.15, 101, 108–112]). The interpretation of TMDSC measurements in the glass-transition region has been recently discussed and reviewed by *Hutchinson* and *Montserrat* [19.113–116]. The reversing heat flow (RHF) through the T_g region exhibits a step-like change and represents the change in the heat capacity. The hysteresis effects associated with thermal history seem to be less important in the RHF but present in the NHF. The measurement of T_g from the RHF in TMDSC experiments shows only a weak dependence on glass aging and thermal history [19.117–119], which is a distinct advantage of this technique. The interpretation of the NHF has been more difficult but it is believed that it provides a qualitative indication of the enthalpy loss during the annealing period below T_g [19.103] though more research is needed to clarify its interpretation. Figure 19.19 shows a typical MDSC result through the glass-transition region of $\text{Se}_{99.5}\text{As}_{0.5}$ glass.

It is important to emphasize that ideally the underlying heating rate in TMDSC experiments should be as small as possible. In this way we can separate the conventional DSC experiment, which also takes place during TMDSC measurements, from the dynamic, frequency-controlled TMDSC experiment. The oscillation amplitude A in the TMDSC must be properly chosen so that the C_P measurements do not depend on A ; typically $A = \pm 1.0^\circ\text{C}$ [19.61]. The oscillation period P should be chosen to ensure that there are at least four full modulations within the half width of the temperature transition, that is, a minimum of eight oscillations over

Fig. 19.19 A typical TMDSC scan

the T_g range, as can be seen in the example in Fig. 19.19 which has a particularly narrow glass-transition range and required a $P = 60$ s. The difference between the average specific capacity, as determined from the conventional DSC heat flow, and the complex heat capacity, as determined from TMDSC RHF, in the T_g region is substantial [19.115]. The influence of experimental conditions on TMDSC measurements have been well discussed in the literature [19.120].

The glass transition T_g as observed in DSC scans is well known to depend on thermal history. The classical well-known example is the fact that the T_g value determined by DSC under a heating scan at a given rate r is different from that determined under a cooling scan at a rate $q = r$. Further, T_g determined in a DSC heating scan also depends on aging. The case for As_2Se_3 is well documented [19.60]. Figure 19.20 shows an example in which the T_g values for vitreous As_2Se_3 determined in TMDSC heating and cooling scans are approximately the same for a given modulation

Fig. 19.20 Typical TMDSC heating and cooling scans on As_2Se_3 glass

period P , within experimental errors. T_g depends only on the modulation frequency $\omega (= 2\pi/P)$ provided that the underlying heating or cooling scan is sufficiently slow, usually less than $1^\circ\text{C}/\text{min}$. Other examples are also available in the literature for both glasses and polymers [19.121, 122]. The T_g measurement in the TMDSC experiments represents the relaxation processes associated with the temperature modulation, and not the underlying heating rate as in the conventional DSC. For example, T_g in TMDSC represents a temperature where the relaxation time τ is comparable with the modulation period P . Above T_g , $\tau \ll P$ and below T_g , $\tau \gg P$, and in the T_g region $\tau \approx P$. As P (or ω) is varied, from experiment to experiment, different values of τ satisfy $\tau \approx P$ and hence T_g depends on ω . It is possible to examine the shift in T_g with ω , and then plot $\ln \omega$ versus $1/T_g$ to extract the activation energy of the relaxation time τ , as shown for As_2Se_3 [19.61]. T_g that is observed in conventional DSC experiments is associated with the devitrification (on heating) and vitrification (on cooling) of the structure, whereas T_g in TMDSC experiments represents a dynamic glass-transition temperature; it is important to arrange the experimental conditions so that the two processes are separated in the measurement [19.123].

While a single phenomenological relaxation time provides a convenient description of the overall glass-transformation behavior, a more complete description necessarily involves incorporating a distribution of relaxation times, as discussed in [19.116].

19.5.3 Tzero Technology

It is well known that there is a thermal lag between the sample and temperature-control sensors in the DSC and most DSCs require calibration at the heating rate to be used. Alternatively, calibration at multiple rates is required to correct for the heating rate dependence of the thermal lag. Without this calibration, there is considerable error in the temperature data in changing from one heating rate to another. This problem is especially acute in cooling experiments due to the thermal lag being in the opposite direction to that of heating, thereby doubling the lag effect. The lag problem has been solved in a new DSC called the *Tzero technology*, as developed by TA Instruments [19.124, 125]. With the Q-series DSC system, an additional thermocouple on the DSC sensor allows a complete calibration of the DSC cell and compensation for all thermal lags, including those caused by the encapsulated sample. This means that, for all practical purposes, the DSC can be

calibrated at any reasonable heating rate, and the DSC temperature data will be correct within a few tenths of a Celsius degree for data taken at other heating or cooling rates. Inasmuch as advanced Tzero compensates for the effect of pan thermal mass and coupling, it is possible to calibrate using one pan type and then use another pan type without incurring substantial errors. In summary, since the Tzero technology uses more information in the DSC measurement, it is more accurate under a wider range of conditions compared with the ordinary DSC without calibration under those specific conditions.

The thermal lag error is proportional to heat flow, heating rate, and to the mass of the sample/pan system.

Hence, this error becomes greatest with fast scanning rates, large sample masses, massive sample pans, or sample specimens with an especially high heat capacity. The thermal lag error is also proportional to the thermal resistance between the sample and sensors so it is made worse by using pans made of poor thermal conductivity or pans making poor thermal contact. However, even in ordinary polymer samples, using optimally coupled aluminum pans, the error produced could be more than two Celsius degrees because of poor thermal conductivity; for other samples it could be several times larger. In summary, the Tzero technology has enabled better DSC experiments to be carried out.

20. Electrical Characterization of Semiconductor Materials and Devices

Semiconductor materials and devices continue to occupy a preeminent technological position due to their importance when building integrated electronic systems used in a wide range of applications from computers, cell-phones, personal digital assistants, digital cameras and electronic entertainment systems, to electronic instrumentation for medical diagnostics and environmental monitoring. Key ingredients of this technological dominance have been the rapid advances made in the quality and processing of materials – semiconductors, conductors and dielectrics – which have given metal oxide semiconductor device technology its important characteristics of negligible standby power dissipation, good input–output isolation, surface potential control and reliable operation. However, when assessing material quality and device reliability, it is important to have fast, nondestructive, accurate and easy-to-use electrical characterization techniques available, so that important parameters such as carrier doping density, type and mobility of carriers, interface quality, oxide trap density, semiconductor bulk defect density, contact and other parasitic resistances and oxide electrical integrity can be determined. This chapter describes some of the more widely employed and popular techniques that are used to determine these important parameters. The techniques presented in this chapter range in both complexity and test structure requirements from simple current–voltage measurements to more sophisticated

low-frequency noise, charge pumping and deep-level transient spectroscopy techniques.

The continued evolution of semiconductor devices to smaller dimensions in order to improve performance – speed, functionality, integration density and reduced cost – requires layers or films of semiconductors, insulators and metals with increasingly high quality that are well-characterized and that can be deposited and patterned to very high precision. However, it is not always the case that improvements in the quality of ma-

terials have kept pace with the evolution of integrated circuit down-scaling. An important aspect of assessing the material quality and device reliability is the development and use of fast, nondestructive and accurate electrical characterization techniques to determine important parameters such as carrier doping density, type and mobility of carriers, interface quality, oxide trap density, semiconductor bulk defect density, con-

tact and other parasitic resistances and oxide electrical integrity. This chapter will discuss several techniques that are used to determine these important parameters. However, it is not an extensive compilation of the electrical techniques currently used by the research and development community; rather, it presents a discussion of some of the more widely used and popular ones [20.1–4].

An important aspect of electrical characterization is the availability of appropriate test components [20.1–4]. In this chapter, we concentrate on discussing techniques that use standard test devices and structures. In addition, we will use the MOSFET whenever possible because they are widely available on test chips. This is also motivated by the fact that MOSFETs continue to dominate the semiconductor industry for a wide range of applications from memories and microprocessors to signal and imaging processing systems [20.5]. A key reason for this dominance is the excellent quality of the silicon wafers and the silicon–silicon dioxide interface, both of which play critical roles in the performance and reliability of the device. For example, if the interface has many defects or interface states, or it is rough, then the device’s carrier mobility decreases, low-frequency noise increases and its performance and reliability degrades. In particular, it is not only the interface that is important, but also the quality of the oxide; good-quality oxide prevents currents from flowing between the gate and substrate electrodes through the gate oxide. Both interface and oxide quality allows for excellent isolation between the input and output terminals of the MOSFETs, causing it to behave as an almost ideal switch. Therefore, it is important to have good experimental tools to study the interface properties and the quality of the gate dielectric.

Electrical characterization of semiconductors and the semiconductor–dielectric interface is important for a variety of reasons. For example, the defects at and in the interfacial oxide layer in silicon–silicon dioxide (Si–SiO₂) systems and in the bulk semiconductor play critical roles in their low-frequency noise, independent of whether the device is surface-controlled such as a MOSFET, or a bulk transport device such as a polysilicon emitter bipolar junction transistor (PE BJT). These defects can affect the charge transfer efficiency in charge coupled devices (CCDs), p–n photodiodes or CMOS imagers, and can be the initiation point of catastrophic failure of oxides. Interface and bulk states can act as scattering centers to reduce the mobility in MOSFETs, thus affecting their performance parameters such as switching speed, transconductance and noise.

This chapter is devoted to the electrical characterization of semiconductors, insulators and interfaces. In the first part (Sects. 20.1 and 20.2), the basic electrical properties of materials (such as resistivity, concentration and mobility of carriers) are studied. The main measurement techniques used to determine these electrical parameters are presented. Due to its increasing importance in modern ultrasmall geometry devices, electrical contacts are also studied. All of the characterization techniques presented in this first part are associated with specially designed test structures. In the second part (Sects. 20.4 to 20.7), we use active components such as capacitors, diodes and transistors (mainly MOSFETs) in order to determine more specific electrical parameters such as traps, oxide quality and noise level that are associated with material or devices. Of course this involves specific measurement techniques that are often more sophisticated than those discussed in the previous two sections.

20.1 Resistivity

Resistivity is one of the most important electrical parameters of semiconductors [20.1–4]. First, we present the basic physical relations concerning the bulk resistivity. The main electrical measurement techniques are then described: the two oldest ones that are still relevant today – the *four-point-probe* technique and the *van der Pauw* technique – and then the *spreading resistance* technique. Second, because it is closely linked with bulk resistivity measurement techniques and it is increasingly important in modern ultrasmall geometry devices, contact resistivity will be presented. Special attention will be given to

Kelvin contact resistance (KCR) measurement and the *transmission line measurement (TLM)* techniques.

20.1.1 Bulk Resistivity

Physical Approach, Background and Basics
The bulk resistivity ρ is an intrinsic electrical property related to carrier drift in materials such as metals and semiconductors [20.6]. From a macroscopic point of view, the resistivity ρ can be viewed as the normalization of the bulk resistance (R) by its geometrical dimensions

– the cross-sectional area ($A = Wt$) through which the current flows, and the distance between the two ideal contacts L , as shown in Fig. 20.1. The resistivity is given by

$$\rho = \frac{RA}{L} \text{ in } \Omega\text{m or commonly } \Omega\text{cm.} \quad (20.1)$$

For thin semiconductor layers, the sheet resistivity ρ_s is often used instead of the bulk resistivity ρ . The sheet resistivity ρ_s is the bulk resistivity divided by the sample's thickness t . This normalized parameter is related to the resistance of a square of side L . For this particular geometry in Fig. 20.1, since $A = Wt$, then $\rho_s = R_{\square}$, the sheet resistance. The unit of sheet resistance is Ω/square or Ω/\square . The parameter R_{\square} is convenient for integrated circuit designers because it allows them to quickly design the geometry for a specific value of resistance using very thin implanted or diffused semiconductor regions or polycrystalline layers. Resistivity (or its inverse, the conductivity σ in $\Omega^{-1}\text{cm}^{-1}$ or S/cm) and its variation with temperature is often used to classify material into metals, semiconductors and insulators.

Since different semiconductors can have the same resistivity, and also different values of resistivity can be found for a given semiconductor, depending on how it is processed for example, then resistivity is not a fundamental material parameter. From solid state theory, in the case of homogeneous semiconductor materials, the resistivity expresses the proportionality between the applied electric field E and the drift current density J ; that is, $J = (1/\rho) E$. It can be defined by the microscopic relation:

$$\rho = \frac{1}{q(n\mu_n + p\mu_p)}, \quad (20.2)$$

where q is the electronic charge, n and p are the free electron and hole concentrations, and μ_n and μ_p are the electron and hole drift mobilities, respectively. In this way, the resistivity is related to fundamental semiconductor parameters: the number of free carriers, and their

ability to move in the lattice when an electric field is applied.

In n-type or donor (N_D)-doped, or p-type or acceptor (N_A)-doped semiconductors, the free carrier densities are determined by the ionized impurities (N_D or $N_A \gg$ the intrinsic carrier concentration n_i), then (20.2) can be simplified to:

$$\rho \approx \frac{1}{qn\mu_n}, \text{ for an n-type semiconductor,} \quad (20.3a)$$

$$\text{and } \rho \approx \frac{1}{qp\mu_p}, \text{ for an p-type semiconductor.} \quad (20.3b)$$

In the following sections, only single-type semiconductors will be studied. This corresponds to most semiconductor materials used in electronic and optoelectronic devices because either $N_D \gg N_A$ or $N_A \gg N_D$ in a typical semiconductor layer.

Measurement Techniques

The simplest way to determine bulk resistivity is to measure the voltage drop along a uniform semiconductor bar through which a DC current I flows, as shown in Fig. 20.1. Thus, the measured resistance and knowledge of the geometrical dimensions can lead to an estimate for the bulk resistivity according to (20.1). Unfortunately the measured resistance (R_{mea}) includes the unexpected contact resistance ($2R_c$), which can be significant for small-geometry samples because R_c is strongly dependent on the metal-semiconductor structure. Therefore, special processing technologies are used to minimize the influence of R_c (see Sect. 20.1.2). Now, the measured resistance is expressed as

$$R_{\text{mea}} = R + 2R_c. \quad (20.4)$$

If probes are used instead of large metal-semiconductor contacts, then the spreading resistance (R_{sp}) under the two probes must also be added, as shown in Fig. 20.2. In this case, (20.4) becomes

$$R_{\text{mea}} = R + 2R_{\text{sp}} + 2R_c, \quad (20.5)$$

where R_{sp} for a cylindrical contact of radius r , and for a semi-infinite sample, it can be expressed by

$$R_{\text{sp}} = \frac{\rho}{4r}. \quad (20.6)$$

For a hemispherical contact of radius r , R_{sp} is given by

$$R_{\text{sp}} = \frac{\rho}{2\pi r}. \quad (20.7)$$

Fig. 20.1 Bulk resistance and its geometrical dimensions

Fig. 20.2 Spreading resistance associated with a probe contact

In both cases, it is very difficult to provide a direct measurement or an accurate model of the contact resistance. So determining the bulk resistivity by this approach is not recommended, except when the spreading resistance is the dominant term in (20.5) and when (20.6) or (20.7) can be applied. In this case, the resistivity is determined by the *spreading resistance* technique measurement. Nevertheless, despite the lack of accuracy of the two contact techniques, it can be sufficient for monitoring some process steps and it is often used in the semiconductor industry as a process monitor.

Four-Point Probe Technique. In order to eliminate or at least minimize the contact contribution to the measured resistance value, techniques based on separate current injection and voltage drop measurements have been developed. First, the two-probe technique can be used, as reported in Fig. 20.1. This measurement is very simple, but it is affected by several parameters: lateral contact geometry, probe spacing, and minority carrier injection near the lateral contacts. The main disadvantage of this technique is the need for lateral contacts. This requirement is overcome with the four-point probe technique, where two probes are used for current injection and the other two probes are used to measure the voltage drop. The more usual probe geometry configuration is when the four probes are placed in a line, as shown in Fig. 20.3.

The voltage at probe 2, V_2 , induced by the current flowing from probe 1 to probe 4 is given by:

$$V_2 = \frac{\rho I}{2\pi} \cdot \left(\frac{1}{s_1} - \frac{1}{s_2 + s_3} \right). \quad (20.8a)$$

The voltage at probe 3 is:

$$V_3 = \frac{\rho I}{2\pi} \cdot \left(\frac{1}{s_1 + s_2} - \frac{1}{s_3} \right). \quad (20.8b)$$

Then, by measuring $V = V_2 - V_3$, the voltage drop between probes 2 and 3, and the current I through probes 1 and 4, the resistivity can be determined using (20.8a)

and (20.8b) as

$$\rho = \frac{2\pi V/I}{\left(\frac{1}{s_1} + \frac{1}{s_2} - \frac{1}{s_2 + s_3} - \frac{1}{s_1 + s_2} \right)} \quad (20.9)$$

Thus, a direct measurement of the resistivity can be made using a high-impedance voltmeter and a current source. When the probe spacings are equal ($s_1 = s_2 = s_3 = s$), which is the most practical case, then (20.9) becomes

$$\rho = 2\pi s \cdot \frac{V}{I}. \quad (20.10)$$

Equations (20.9) and (20.10) are valid only for semi-infinite samples; that is, when both t and the sample surface are very large ($\rightarrow \infty$), and the probes' locations must be far from any boundary. Because these relations can be applied only to large ingots, then in many cases a correction factor f must be introduced in order to take into account the finite thickness and surface of the sample and its boundary effects. Further, for epitaxial layers, f must also consider the nature of the substrate – whether it is a conductor or an insulator. Thus, (20.10) becomes

$$\rho = 2\pi s \cdot \frac{V}{I} \cdot f. \quad (20.11)$$

For a thin semiconductor wafer or thin semiconducting layer deposited on an insulating substrate, and for the condition $t < s/2$, which represents most practical cases because the probe spacing s is usually on the order of a millimeter, then the correction factor due to the thickness is

$$f = \frac{(t/s)}{2 \ln 2} \text{ so that } \rho = 4.532t \frac{V}{I}. \quad (20.12)$$

The noninfinite sample surface must be corrected if the ratio of the wafer diameter to the probe spacing is not

Fig. 20.3 Linear four-point probe configuration. The sample thickness is t and a is the distance from the edge or boundary of the sample

greater than 40, otherwise a correction factor of less than unity has to be introduced [20.3].

If the probe header is too close to any boundary, then (20.12) is no longer valid and another correction factor must be introduced. This correction factor is close to 1 until the ratio a/s is greater than 2, where a is the distance from the edge of the sample that is shown in Fig. 20.3. A study of various 8 inch n- and p-type silicon wafers have demonstrated that the edge exclusion limit is 5 mm [20.7].

In the case of a different arrangement of probes, for instance a square array or when a different measurement configuration of the four-point collinear probes is used, such as current injection between probes 1 and 3, other specific correction factors are required. Here, rather than detail all the different correction factors, complementary information can be found in Chap. 4 of [20.4] and Chap. 1 of [20.3].

Taking into account the appropriate correction factors as well as some specific material parameters such as hardness or surface oxidation, it is possible to map the resistivities of different types of semiconductor wafers or deposited semiconductor layers with an accuracy better than 1% over a large range of resistivity values using commercial equipment and appropriate computational techniques.

Van der Pauw Technique. Based on the same basic principle of separating the current injection and voltage measurement, the *van der Pauw* [20.8] measurement technique allows for the determination of resistivity on a sample of arbitrary shape using four small contacts placed on the periphery, as shown in Fig. 20.4. Then, the resistivity of a uniform sample of thickness t is given

Fig. 20.4 van der Pauw method for an arbitrarily shaped sample

by

$$\rho = \frac{\pi t}{\ln 2} \frac{(R_A + R_B)}{2} f. \quad (20.13)$$

Here, R_A and R_B are resistances measured by injecting current on two adjacent contacts and by measuring the voltage drop on the two remaining ones. With the notation in Fig. 20.4, one can define

$$R_A = \frac{V_3 - V_4}{I_{1,2}}, \quad R_B = \frac{V_4 - V_1}{I_{2,3}}, \quad (20.14)$$

f is a correction factor that is

$$\text{a function of the ratio} \quad R_f = \frac{R_A}{R_B}.$$

with R_f obtained from

$$\frac{(R_f - 1)}{(R_f + 1)} = \frac{f}{\ln 2} \cdot \operatorname{arccosh} \left(\frac{\exp(\ln 2 / f)}{2} \right). \quad (20.15)$$

In the case of samples with symmetrical geometries, and when the contacts are also symmetrical, as shown in Fig. 20.5, then $R_A = R_B$, $R_f = 1$ and $f = 1$, and (20.13) becomes

$$\rho = \frac{\pi t}{\ln 2} R_A = 4.532tR_A \quad (20.16)$$

In order to minimize errors caused by the finite dimensions of the contacts (since ideally the contact area should be zero) and the finite thickness of the sample, then the distance between the contacts must be larger than both the diameter and the thickness of the contact. Also, the cloverleaf configuration in Fig. 20.5d is recommended to prevent contact misalignment, but this configuration requires a more complicated patterning technology.

The main advantage of the *van der Pauw* technique compared to the four-point probe technique is its use of a smaller area for the test structure. Therefore, this measurement technique is often used in integrated circuit technology. Also, because of its simple structure, the Greek cross configuration in Fig. 20.5b is

Fig. 20.5a–d Symmetrical van der Pauw structures: (a) square, (b) Greek cross, (c) circle and (d) cloverleaf

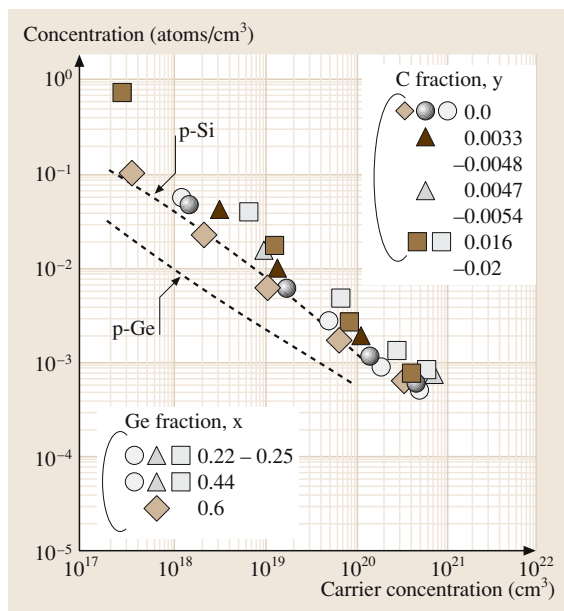

Fig. 20.6 Resistivity versus carrier concentration in $\text{Si}_{1-x}\text{Ge}_x\text{C}_y$ films obtained using a cloverleaf van der Pauw structure. These results are from [20.10]

widely used (experimental results obtained on SiGeC epitaxial layers are reported in Fig. 20.6 as an example). However, when narrow arms are used, current crowding at the corners may have a significant influence, and in this case a different Greek cross layout

can be considered to reduce this current crowding effect [20.9].

Spreading Resistance Technique. The spreading resistance technique is based on the modeling of current spreading from a probe tip or a small metallic contact and flowing into a bulk semiconductor, as shown previously in Fig. 20.2. Equations (20.6) and (20.7) presented above are for cylindrical probes and hemispherical probes, respectively. Basically, the principle of this method is opposite to the previous four-contact techniques where the separation of the current injection from the measured voltage drop was used to avoid the spreading resistance. Here, the spreading resistance is expected to be the dominant term in (20.5). Only two contacts are needed: two closely aligned probes, a small top contact probe or a metallic contact and a large bottom contact. In the first case, surface mapping can be performed, but the main use of this compact probe configuration is for resistivity profiling using a bevelled sample [20.3]. The second configuration has been used to measure the substrate resistivity of silicon integrated circuits where simple test structures – for example the square top contact of $25\ \mu\text{m} \times 25\ \mu\text{m}$ and $50\ \mu\text{m} \times 50\ \mu\text{m}$ shown in [20.12] – have been included on a test chip.

More recently, semiconductor resistivity has been nanocharacterized using scanning spreading resistance microscopy (SSRM) with a standard atomic force microscope (AFM) of lateral resolution of 10 to 20 nm. A SSRM image of a $0.5\ \mu\text{m}$ nMOSFET is given in

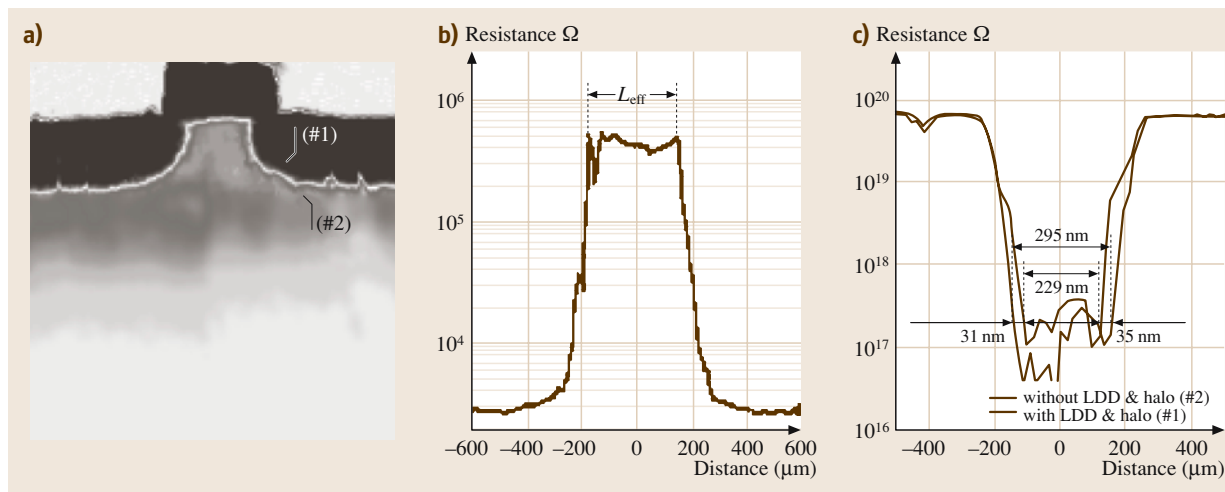

Fig. 20.7 (a) SSRM resistance image (scan size: $1.5\ \mu\text{m} \times 1.5\ \mu\text{m}$) of a $0.5\ \mu\text{m}$ nMOSFET; (b) lateral section taken 10 nm under the gate oxide of the same transistor; (c) lateral carrier concentration profiles measured with SSRM 10 nm under the gate oxide for two $0.35\ \mu\text{m}$ nMOSFETs (with and without halo and LDD process). After [20.11]

Fig. 20.7a [20.11]. The resistance is low in the highly doped regions (dark) and high in the lower doped regions (bright): source, drain, gate and well regions are clearly observed in Fig. 20.7a or the resistance profile in Fig. 20.7b. With such a high resolution, scanning the lateral and vertical diffusion of dopants in active regions of submicron transistors is possible. An example is shown in Fig. 20.7c where the extra implantations [halo and lightly doped drain (LDD)] in a $0.35\text{ }\mu\text{m}$ nMOSFET process are clearly visible and result in a change of L_{eff} from 295 nm without extra implantations to 229 nm with the extra implantations.

20.1.2 Contact Resistivity

The contact resistance of an active device and interconnection becomes larger as the dimensions are scaled down. As a consequence, the performance of single transistors as well as integrated circuits can be seriously limited by increasing RC time constants and power consumption. This is of major interest for the semiconductor industry, as reported by the International Technology Roadmap for Semiconductors, ITRS 2001 [20.5], and in [20.13].

Contact Resistance Elements

Basically, the contact resistance R_c is the resistance localized from a contact pad, a probe or from the metalization process to an active region. However, it does not include all of the access resistances between these two regions, as shown in Fig. 20.8a for a horizontal contact and Fig. 20.8b for a vertical contact.

Starting from the contact pad (Fig. 20.8a and Fig. 20.9), the contact resistance includes the resistance of the metal R_m , the interfacial metal-semiconductor resistance R_i , and the resistance associated with the semiconductor just below the contact in the contact region R_{sc} . Thus, the contact resistance can be expressed

Fig. 20.8 (a) Horizontal contact and (b) vertical contact. Black indicates the metallic conductor, white the semiconductor material or an insulator

Fig. 20.9 Different components of the contact resistance

as

$$R_c = R_m + R_i + R_{sc} . \quad (20.17)$$

The last component R_{sc} cannot be accurately defined because the boundary between the contact and access regions is very difficult to determine due to (for example) interdiffusion of metal and semiconductor atoms, and because the current flow into this region is not homogeneous due to current spreading and lateral or vertical current crowding at the periphery of the contact. The relative importance of each component of R_c is strongly dependent on different parameters of the process itself – annealing temperature, doping density and the geometry used (lateral or vertical).

When comparing different contact technologies and different contact areas, the most convenient parameter to use is the contact resistivity ρ_c , which is referred to as the specific contact resistance in $\Omega\text{ cm}^2$, and ρ_c is given by

$$\rho_c = R_c A_{\text{ceff}} , \quad (20.18)$$

where A_{ceff} is the effective contact area; that is, the current injection area. The concept of an effective contact area can be approximated by the contact geometry in the case of a vertical contact in Fig. 20.8b. However, A_{ceff} is more difficult to specify for a lateral contact, where a transfer length L_T , representing the length where the current flow transfers from the contact into the semiconductor just underneath, must be introduced, as shown in Fig. 20.8a. L_T is defined as the length over which the voltage drops to e^{-1} of its value at the beginning of the contact [20.3], and is given by

$$L_T = \sqrt{\frac{\rho_c}{\rho_{sc}}} , \quad (20.19)$$

where ρ_{sc} is the sheet resistivity of the semiconductor below the contact.

Because of its various components, it is difficult to accurately model the contact resistivity. Nevertheless,

a theoretical approach to the interfacial resistivity [see R_i in (20.17)], ρ_i , can be determined from the well-known Schottky theory of metal–semiconductor contacts. The interfacial resistivity ρ_i is defined by

$$\rho_i = \left. \frac{\partial V}{\partial J} \right|_{V=0}. \quad (20.20)$$

This metal–semiconductor structure is equivalent to an abrupt p-n junction. According to the Schottky theory (for more details see Chap. 5 of [20.14]), the J – V characteristic of a metal–semiconductor contact in the case of a low-doped semiconductor is given by

$$J = A^* T^2 \exp\left(-\frac{q\phi_B}{kT}\right) \left[\exp\left(\frac{qV}{kT}\right) - 1 \right], \quad (20.21)$$

where A^* is Richardson's constant, and T the absolute temperature. ϕ_B is the barrier height formed at the metal–semiconductor interface – the difference between the vacuum level and the Fermi level of the metal and of the semiconductor materials respectively, and ϕ_B is given by

$$\phi_B = \phi_M - \chi \quad (20.22)$$

where ϕ_M is the metal work function and χ the semiconductor electron affinity.

The energy band diagram for a low-doped n-type semiconductor–metal contact is shown in Fig. 20.10. In this case, the current transport is dominated by the thermionic emission current, resulting in a rectifying contact.

Thus, when the conduction mechanism is controlled by the thermionic emission, the interfacial resistivity in (20.20) is simply obtained from the derivative of (20.21), and $\rho_{i,TE}$ is

$$\rho_{i,TE} = \frac{k}{qA^*T} \exp\left(\frac{q\phi_B}{kT}\right) \quad (20.23)$$

Due to the presence of surface states, the barrier height ϕ_B is positive and weakly dependent on the metal–semiconductor material. ϕ_B is $\approx 2E_g/3$ for an n-type

Fig. 20.10 Energy-band diagram of an n-type semiconductor–metal contact and related rectifying contact. W is the width of the depletion layer

Fig. 20.11 Energy-band diagram of an n^+ -n semiconductor–metal structure and related ohmic contact

semiconductor and $\approx E_g/3$ for a p-type semiconductor. Therefore, high values of interfacial resistivity $\rho_{i,TE}$ are usually obtained except when narrow bandgap semiconductors are used.

The way to fabricate ohmic contacts with low contact resistivity values is to process the metal on a heavily doped semiconductor layer. In this case, the depletion width decreases ($W \approx N_D^{-1/2}$) and the probability of carrier tunneling through the barrier increases. Thus, the conduction mechanism is dominated by tunneling, as shown in Fig. 20.11.

The electron tunneling current is expressed as

$$J_{\text{tun}} \approx \exp\left(\frac{q\phi_B}{E_{00}}\right), \quad (20.24)$$

where

$$E_{00} = \frac{q\hbar}{2} \sqrt{\frac{N_D}{\epsilon_s m_n^*}}, \quad (20.25)$$

ϵ_s is the permittivity of the semiconductor and m_n^* is the effective mass of the electron.

From (20.20), (20.24) and (20.25), the interfacial resistivity $\rho_{i,T}$ is found to be

$$\rho_{i,T} \propto \frac{2\sqrt{\epsilon_s m_n^*}}{\hbar} \cdot \frac{\phi_B}{\sqrt{N_D}}. \quad (20.26)$$

Comparing $\rho_{i,TE}$ from (20.23) to $\rho_{i,T}$ from (20.26), we see that a highly doped layer can significantly reduce the interfacial resistivity. For $N_D \geq 10^{19} \text{ cm}^{-3}$, the tunneling process dominates the interfacial resistivity, while for $N_D \leq 10^{17} \text{ cm}^{-3}$, the thermionic emission current is dominant.

As most semiconductors such as Si, SiGe, GaAs, InP are of relatively wide bandgap, the deposition of a heavily doped layer before the metallization is commonly used in order to form a tunneling contact. For compound semiconductor manufacturing processes, the contact layer is generally formed from the same semiconductor material, or at least from the same material as the substrate. For silicon and related materials such

as SiGe alloys or polysilicon, silicidation techniques are commonly used to make the contact layer with very thin silicide layers such as CoSi₂ or TiSi₂ layers.

Measurement Techniques

As mentioned above, it is difficult to accurately model the contact resistance, so direct measurements of the contact resistance or of the contact resistivity are of great importance. The two main test structures used to

Fig. 20.12 Cross Kelvin resistor test structure

Fig. 20.13 Transmission line model (TLM) test structure

Fig. 20.14 Determination of the sheet resistivity and characterization of the contact using a TLM test structure

determine contact characteristics will now be discussed: the *cross Kelvin resistor (CKR) test structure* and the *transmission line model (TLM) structure*.

Kelvin Test Structure. The Kelvin test structure, also referred to as the cross Kelvin resistor (CKR) test structure, is shown in Fig. 20.12. The contact resistance R_c is determined from the potential drop in the contact window (V_{34}) when a current I is forced through the contact window from contact pad 1 to pad 2, and R_c is

$$R_c = \frac{V_{34}}{I} . \quad (20.27)$$

Therefore, a measure of R_c and knowledge of the contact area A allows for direct extraction of the contact resistivity ρ_c , given by

$$\rho_c = R_c A . \quad (20.28)$$

This basic approach is not valid when parasitic effects are present. One of the main problems is current crowding around the contact. In order to extract accurate values for the contact resistivity using Kelvin test structures, it is necessary to take into account the two-dimensional current-crowding effect. This is achieved using the results from numerical simulations [20.15]. Nevertheless, the development of ohmic contacts with very low values of contact resistivities require complex technology with different materials and usually with several interfaces. In this case, a large discrepancy between the extracted and the measured contact parameters can be found [20.15, 16]. To improve the accuracy, three-dimensional models are now used to take into account the different interfacial and vertical parasitic effects [20.17].

Transmission Line Model Test Structures. The transmission line model test structure (TLM) consists of depositing a metal grid pattern of unequal spacing L_i between the contacts. This leads to a scaled planar resistor structure. Each resistor changes only by its distance L_i between two adjacent contacts, as shown in Fig. 20.13, and it can be expressed by

$$R_i = \frac{\rho_s L_i}{W} + 2R_c \quad (20.29)$$

Then, by plotting the measured resistances as a function of the contact spacing L_i , and according to (20.29), the layer sheet resistivity ρ_s and the contact resistance R_c can be deduced from the slope and from the intercept at

$L_i = 0$ respectively, as shown in Fig. 20.14:

$$\begin{aligned} \text{Slope} &= \frac{\rho_s}{W}; R_i(\text{intercept}) = 2R_c; \\ \text{and } |L_i(\text{intercept})| &= 2L_T \end{aligned} \quad (20.30)$$

As discussed in Sect. 20.1.2, the most suitable parameter for characterizing a contact is its contact resistivity (ρ_c) or the specific contact resistance ($R_c A_{\text{ceff}}$), given by

$$\rho_c = R_c A_{\text{ceff}} = R_c W L_T \quad (20.31)$$

As shown in Fig. 20.8a, for a planar resistor, the effective contact area requires the notion of the transfer length L_T . According to (20.19), and assuming that the sheet resistance under the contact ρ_{sc} is equal to the

sheet resistance between the contacts ρ_s , then L_T can be expressed by (20.19).

Therefore, the substitution of R_c into (20.31) in (20.29) leads to

$$R_i = \frac{\rho_s}{W} L_i + \frac{\rho_s}{W} 2L_T \quad (20.32)$$

Now, extrapolation to $R_i = 0$ allows us to determine the value of L_T . The main advantage of the *TLM* method is its ability to give two main electrical parameters, the resistivity of the semiconductor contact layer ρ_s and the contact resistance R_c . However, this is done at the expense of a questionable assumption that the sheet resistance under the contact must be equal to the sheet resistance between the contacts. More on this technique can be found in [20.3].

20.2 Hall Effect

As mentioned before, the resistivity of a semiconductor is not a fundamental material parameter. One can consider the carrier density (n or p) or the carrier mobility (μ_n or μ_p) to be fundamental or microscopic parameters. For a semiconductor material, the resistivity is related to these two parameters (density and mobility) by (20.2). The strength of the Hall effect is to directly determine the sheet carrier density by measuring the voltage generated transversely to the current flow direction in a semiconductor sample when a magnetic field is applied perpendicularly, as shown in Fig. 20.15a. Together with a resistivity measurement technique such as the four-point probe or the van der Pauw technique, Hall measurements can be used to determine the mobility of a semiconductor sample.

In modern semiconductor components and circuits, knowledge of these two fundamental parameters n/p and μ_n/μ_p is critical. Currently, Hall effect measurements are one of the most commonly used characterization tools in the semiconductor industry and research laboratories. This is not just because of the parameters that can be extracted for use in device modeling or materials characterization, but also because of the quantum Hall effect (QHE) in condensed matter physics [20.18]. Moreover, in the applied electronics domain, one should note the development of different sensors based on the physical principle of the Hall effect, such as commercial CMOS Hall sensors.

As is very often the case, the development of a characterization technique is related to its cost, simplicity

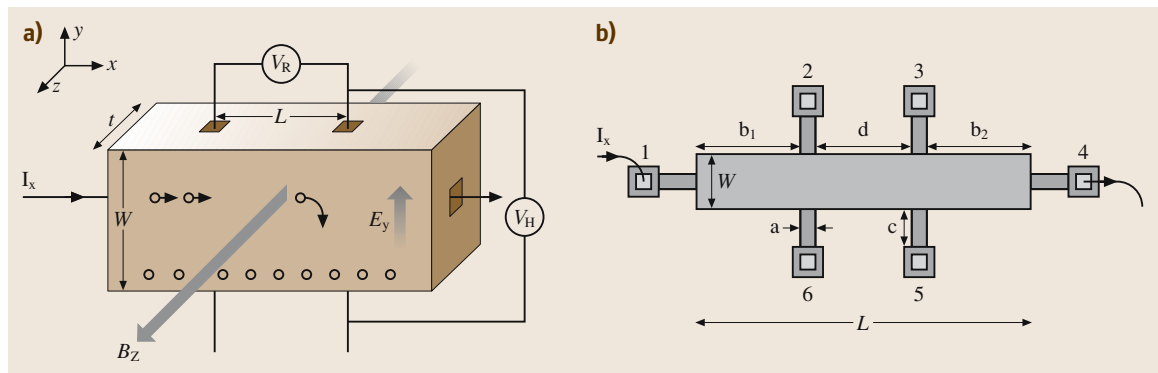

Fig. 20.15 (a) Representation of the Hall effect in an p-type bar-shaped semiconductor. (b) Practical sample geometry: a six-terminal Hall-bar geometry

of implementation and ease of use. Since these practical characteristics are satisfied even when specially shaped samples are required, then the Hall effect measurement technique has become a very popular method of characterizing materials.

In this section, we will first present the physical principle of the Hall effect. Then we will show how it can be used to determine the carrier density and mobility. Finally, the influence of the Hall scattering factor will be presented, followed by some practical issues about the implementation of the Hall effect method.

20.2.1 Physical Principles

The Hall effect was discovered by *Hall* in 1879 [20.19] during an experiment on current transport in a thin metal strip. A small voltage was generated transversely when a magnetic field was applied perpendicularly to the conductor.

The basic principle of this Hall phenomenon is the deviation of some carriers from the current line due to the Lorentz force induced by the presence of a transverse magnetic field. As a consequence, a voltage drop V_H is induced transversely to the current flow. This is shown in Fig. 20.15a for a p-type bar-shaped semiconductor, where a constant current flow I_x in the x -direction and a magnetic field in the z -direction results in a Lorentz force on the holes. If both holes and electrons are present, they deviate towards the same direction. Thus, the directions of electrical and magnetic fields must be accurately specified.

The Lorentz force is given by the vector relation

$$F_L = q(\mathbf{v} \times \mathbf{B}) = -qv_x B_z, \quad (20.33)$$

where v_x is the carrier velocity in the x -direction. Assuming a homogeneous p-type semiconductor

$$v_x = \frac{I}{qtWp}. \quad (20.34)$$

As a consequence, an excess surface electrical charge appears on one side of the sample, and this gives rise to an electric field in the y -direction E_y . When the magnetic force F_L is balanced by the electric force F_{EL} , then the Hall voltage V_H is established, and from a balance between F_L and F_{EL} , we get

$$F = F_L + F_{EL} = -qv_x B_z + qE_y = 0, \quad (20.35)$$

$$\text{so } E_y = \frac{BI}{qtWp}. \quad (20.36)$$

Also, the Hall voltage V_H is given by

$$V_H = V_y = E_y W = \frac{BI}{qt p}. \quad (20.37)$$

So if the magnetic field B and the current I are known, then the measurement of the Hall voltage gives the hole sheet concentration p_s from

$$p_s = pt = \frac{BI}{qV_H}. \quad (20.38)$$

If the conducting layer thickness t is known, then the bulk hole concentration can be determined [see (20.40)] and expressed as a function of the Hall coefficient R_H , defined as

$$R_H = \frac{tV_H}{BI} \quad (20.39)$$

$$\text{and } p = \frac{1}{qR_H} \quad (20.40)$$

Using the same approach for an n-type homogeneous semiconductor material leads to

$$R_H = -\frac{tV_H}{BI}, \quad (20.41)$$

$$\text{and } n = -\frac{1}{qR_H} \quad (20.42)$$

Now, if the bulk resistivity ρ is known or can be measured at the same time using a known sample such as a Hall bar or van der Pauw structure geometry in zero magnetic field, then the carrier drift mobility can be obtained from

$$\mu = \frac{|R_H|}{\rho} \quad (20.43)$$

There are two main sample geometries commonly used in Hall effect measurements in order to determine either the carrier sheet density or the carrier concentration if the sample thickness is known, and the mobility. The first one is the van der Pauw structure presented in Sect. 20.1.1. The second one is the Hall bar structure shown in Fig. 20.15b, where the Hall voltage is measured between contacts 2 and 5, and the resistivity is measured using the four-point probes technique presented in Sect. 20.1.1 (contacts 1, 2, 3 and 4). Additional information about the shapes and sizes of Hall structures can be found in [20.3, 4, 20].

Whatever the geometry used for Hall measurements, one of the most important issues is related to the offset voltage induced by the nonsymmetric positions of the contact. This problem, and also those due to spurious voltages, can be controlled by two sets of

measurements, one for a magnetic field in on direction and another for a magnetic field in the opposite direction.

The Hall effect has also been investigated on specific structures, and an interesting example can be found in reference [20.21], where a Hall bar structure was combined with a double-gate n-SOI MOSFET. This was done in order to understand the mobility behavior in ultra-thin devices and to validate the classical drift mobility extraction method based on current-voltage measurements.

In the Hall effect experiment, the measurement of the Hall coefficient R_H leads to the direct determination of the carrier concentration and mobility. Moreover, the sign of R_H can be used to determine the type of conductivity of the semiconductor sample. If various types of carriers are present, then the expression for R_H becomes more complex and approximations in the limit of low and high magnetic field are necessary (see Chap. 8 of [20.3]).

We have so far discussed the Hall effect on a uniformly doped substrate or single semiconductor layer deposited on an insulating or semi-insulating substrate. In the case of a semiconductor layer deposited on a semi-conducting substrate of opposite doping type, Hall effect measurements can be performed if the space charge region can act as an insulator. In the case of multilayers, the problem is more difficult, but an approximation for transport experiments has been developed for two-layer

structures [20.23] and applied to different MESFET structures, for instance [20.24].

20.2.2 Hall Scattering Factor

The relations presented above are based on an energy-independent scattering mechanism. With this assumption made, the Hall carrier concentration and the Hall mobility are equal to the carrier concentration and the carrier drift mobility. When this assumption is no longer valid, these electrical parameters are different and the Hall scattering factor r_H must be taken into account. In this case (20.40), (20.42) and (20.43) must be modified as follows:

$$p_H = \frac{r_H}{qR_H} = r_H p, \quad (20.44)$$

$$n_H = -\frac{r_H}{qR_H} = r_H n, \quad (20.45)$$

and

$$\mu_H = r_H \frac{|R_H|}{\rho} = r_H \mu. \quad (20.46)$$

The Hall scattering factor [20.25] is related to the energy dependence of the mean free time between carrier collisions $\tau(E)$, and r_H is given by:

$$r_H = \frac{\langle \tau^2 \rangle}{\langle \tau \rangle^2}. \quad (20.47)$$

According to theory [20.3], the Hall scattering factor tends to unity in the limit of high magnetic field. Therefore, r_H at low magnetic fields can be determined by measuring the Hall coefficient in the limit of both high and low magnetic fields [20.25] using:

$$r_H = \frac{R_H(B)}{R_H(\infty)} \quad (20.48)$$

Depending on the scattering mechanism involved (lattice, ionized or neutral impurity, electron, or phonon scattering), r_H is found to vary between 0.6 and 2 [20.26]. However, due to valence band distortion effects, values as low as 0.26 have been found in strained p-type SiGe epilayers [20.27]. Therefore, the Hall carrier concentration and especially the Hall mobility must be distinguished from carrier concentration and carrier drift mobility.

Fig. 20.16 Hall mobility as a function of temperature on two SOI films. After [20.22]

As the different scattering mechanisms have different temperature (T) dependences, then the Hall mobility as function of temperature is often used to separate the different scattering processes. An example is given in Fig. 20.16 for silicon-on-insulator (SOI) films [20.22]. The increase in the mobility between 4–45 K, which is given by $\mu \propto T^{2.95}$, is related to the ionized donor scattering mechanism.

The decrease in mobility between 46–120 K given by $\mu \propto T^{-1.55}$ is associated with lattice scattering. However, after 150 K, the rapid decrease in mobility observed, where $\mu \propto T^{-2.37}$, suggests that other scattering mechanisms as well as the lattice scattering mechanism, such as electron or phonon scattering, must be taken into account.

20.3 Capacitance–Voltage Measurements

Capacitance–voltage (C – V) measurements are normally made on metal–oxide semiconductor (MOS) or metal–semiconductor (MS) structures in order to determine important physical and defect information about the insulator and semiconductor materials. For example, high-frequency (HF) and low-frequency (LF) or quasi-static C – V measurements in these structures are used to determine process and material parameters – insulator thickness, doping concentration and profile, density of interface states, oxide charge density, and work function or barrier height. In this section, we describe various C – V measurements and how they can be used to provide process parameters as well as valuable information about the quality of the materials. A typical C – V curve for a MOS capacitor with an n-type semiconductor is shown in Fig. 20.17. For a MOS capacitor with a p-type substrate, the C – V curve be similar to that in Fig. 20.17, but reflected about the y-axis.

20.3.1 Average Doping Density by Maximum–Minimum High-Frequency Capacitance Method

The maximum–minimum high-frequency (HF) capacitance method uses the HF capacitance under strong accumulation (C_{OX}) and strong inversion ($C_{HF,min}$) to determine the average doping density (see [20.29][pp. 406–408]). Note that under strong inversion and at high frequencies, the interface trap capacitance is negligible ($C_{it} \approx 0$). Under strong inversion, the depletion width (w_{max}) is a maximum and so the high frequency capacitance per unit area $C_{HF,min}$ is a minimum, since the minority carriers cannot respond to the high-frequency signal. Since the inversion layer is very thin compared to the depletion layer, then

$$w_{max} = \epsilon_{Si} \left(\frac{1}{C_{HF,min}} - \frac{1}{C_{OX}} \right), \quad (20.49)$$

Fig. 20.17 Typical C – V curve for a MOS capacitor on an n-type substrate. After [20.28]

where ϵ_{Si} is the permittivity of silicon and C_{OX} is the gate oxide capacitance per unit area.

At the conditions for w_{max} , the band bending ψ_{max} is a maximum, and it is

$$\begin{aligned} \psi_{max} &= 2\phi_B + \frac{kT}{q} \ln \left(2 \frac{q}{kT} \phi_B - 1 \right) \\ &= 2 \frac{kT}{q} \left\{ \ln \left(\frac{n}{n_i} \right) + \frac{1}{2} \ln \left[2 \ln \left(\frac{n}{n_i} \right) - 1 \right] \right\}, \end{aligned} \quad (20.50)$$

where $\phi_B = (k_B T/q) \times \ln(n/n_i)$ is the shift of the Fermi level from the intrinsic Fermi level $\phi_i = (E_c - E_v)/2q$ in the bulk of the silicon in the MOS structure due to the doping concentration n , and n_i is the thermally generated carrier concentration in silicon. For a uniformly doped sample,

$$w_{max}^2 = \frac{2\epsilon_{Si}\psi_{max}}{qn} \quad (20.51)$$

and from (20.49) and (20.51), a relation between the doping concentration n and the measured capacitance

Fig. 20.18 Doping concentration n as function of $C_{\text{HF,min}}/C_{\text{OX}}$ with oxide thickness, based on (20.52). After [20.29]

can be established ([20.29], p. 407) as

$$\frac{n}{\ln\left(\frac{n}{n_i}\right) + \frac{1}{2} \ln\left[2 \ln\left(\frac{n}{n_i}\right) - 1\right]} = \frac{4kT}{q^2 \epsilon_{\text{Si}}} \frac{C_{\text{OX}}^2}{\left(\frac{C_{\text{OX}}}{C_{\text{HF,min}}} - 1\right)^2}. \quad (20.52)$$

Equation (20.52) is a transcendental equation in average doping concentration n that can be solved numerically by iteration. Figure 20.18 shows the solutions as function of $C_{\text{HF,min}}/C_{\text{OX}}$ with oxide thickness, and this can be used to obtain the average doping n graphically. Equation (20.52) can be further simplified by neglecting the term $0.5 \ln[2 \ln(n/n_i) - 1]$, and assuming $C_{\text{OX}} = C_{\text{HF,max}}$ [20.30]. Also, an approximation of (20.52) for the average doping concentration n in unit cm^{-3} is obtained in [20.4] and [20.31] for silicon MOS structures at room temperature, and this is given by

$$\begin{aligned} \log_{10}(n) &= 30.38759 + 1.68278 \\ &\quad \times \log_{10}(C_{\text{DM}} - 0.03177) \\ &\quad \times [\log_{10}(C_{\text{DM}})]^2, \end{aligned} \quad (20.53)$$

where the depletion capacitance (per cm^2 of area) C_{DM} is defined as

$$C_{\text{DM}} = \frac{C_{\text{HF,min}} C_{\text{OX}}}{C_{\text{OX}} - C_{\text{HF,min}}}, \quad (20.54)$$

where all capacitances are in units of F/cm^2 .

20.3.2 Doping Profile by High-Frequency and High-Low Frequency Capacitance Methods

The doping profile in the depletion layer can be obtained ([20.29], Sect. 9.4) by assuming that the depletion capacitance per unit area C_{D} and the oxide capacitance per unit area C_{OX} are connected in series; that is, that the measured high frequency capacitance C_{HF} is given by

$$\frac{1}{C_{\text{HF}}} = \frac{1}{C_{\text{D}}} + \frac{1}{C_{\text{OX}}} \Rightarrow \frac{1}{C_{\text{D}}} = \frac{1}{C_{\text{HF}}} - \frac{1}{C_{\text{OX}}}. \quad (20.55)$$

For a particular gate biasing V_{G} of the MOS structure, the depletion thickness $w(V_{\text{G}})$ is obtained from C_{D} as

$$w(V_{\text{G}}) = \epsilon_{\text{Si}} \left(\frac{1}{C_{\text{HF}}} - \frac{1}{C_{\text{OX}}} \right). \quad (20.56)$$

The doping concentration $n(V_{\text{G}})$ is given by the slope of the $(1/C_{\text{HF}})^2$ versus V_{G} characteristic, given by

$$n(w) = \frac{-2}{q \epsilon_{\text{Si}} \frac{\partial}{\partial V_{\text{G}}} \left(\frac{1}{C_{\text{HF}}^2} \right)}. \quad (20.57)$$

Note that a plot of $1/C_{\text{HF}}^2$ versus V_{G} (Fig. 20.19) can yield important information about the doping profile. The average n is related to the reciprocal of the slope in the linear part of the $1/C_{\text{HF}}^2$ versus V_{G} curve, and the intercept with V_{G} at a value of $1/C_{\text{OX}}^2$ is equal to

Fig. 20.19 A $1/C_{\text{HF}}^2$ versus V_{G} plot [20.30]. The slope of the fitted arrow line is proportional to the average doping, and the arrow points to the flat-band voltage V_{FB} , obtained at the V intercept with $1/C_{\text{OX}}^2$, shown with the second horizontal arrow

the flat-band voltage V_{FB} caused by the fixed surface charge Q_{SS} and the gate–semiconductor work function ψ_{MS} [20.3, 30].

Equation (20.57) does not take into account the impact of interface traps, which cause the C – V curve to stretch. The traps are slow and do not respond to the high frequency of the test signal, but they do follow the changes in the gate bias. Therefore, ∂V_G must be replaced with ∂V_{G0} in (20.57), with ∂V_{G0} representing the case when no interface traps are present.

The value of ∂V_{G0} can be obtained by comparing high- and low-frequency (quasi-static) C – V curves for a MOS structure at the same gate biases V_G . Therefore, the ratio $\partial V_{G0}/\partial V_G$ can be found at any gate bias V_G , since the band-bending is the same for both HF and LF capacitances. In [20.29] (Sect. 9.4), it is shown that

$$\frac{\partial V_{G0}}{\partial V_G} = \frac{C_{OX} + C_D}{C_{OX} + C_D + C_{IT}} = \frac{1 - C_{LF}/C_{OX}}{1 - C_{HF}/C_{OX}}. \quad (20.58)$$

In this case (20.57) is modified to

$$n(w) = \frac{-2}{q\epsilon_{Si} \frac{\partial}{\partial V_G} \left(\frac{1}{C_{HF}} \right)} \frac{1 - C_{LF}/C_{OX}}{1 - C_{HF}/C_{OX}} \quad (20.59)$$

as originally proposed in [20.32] and illustrated in Fig. 20.20. As seen from Fig. 20.20, the stretching of the C – V curves due to the interface states induced by stress in Fig. 20.20a causes a disparity in the doping profile in Fig. 20.20b if only the high frequency capacitance is used. The disparity is well-suppressed in Fig. 20.20c by the high–low frequency capacitance measurement, taking into account the stretching of the C – V characteristics. Provided that the depletion layer capacitance is

Fig. 20.21 Limitations on the depth achievable when profiling the doping of silicon MOS structures via C – V measurements at room temperature (After [20.4] p. 86)

measured at a high frequency, the depletion layer width w is still obtained by (20.56).

Note that the maximum depth w_{max} (20.51) and the resolution Δ_w of the doping profile by means of C – V measurements is limited by the maximum band-bending ψ_{max} and the extrinsic Debye length λ_{Debye} , given by (20.50) and (20.60), respectively, and λ_{Debye} is

$$\lambda_{Debye} = \sqrt{\frac{\epsilon_{Si} k T}{q^2 n}}. \quad (20.60)$$

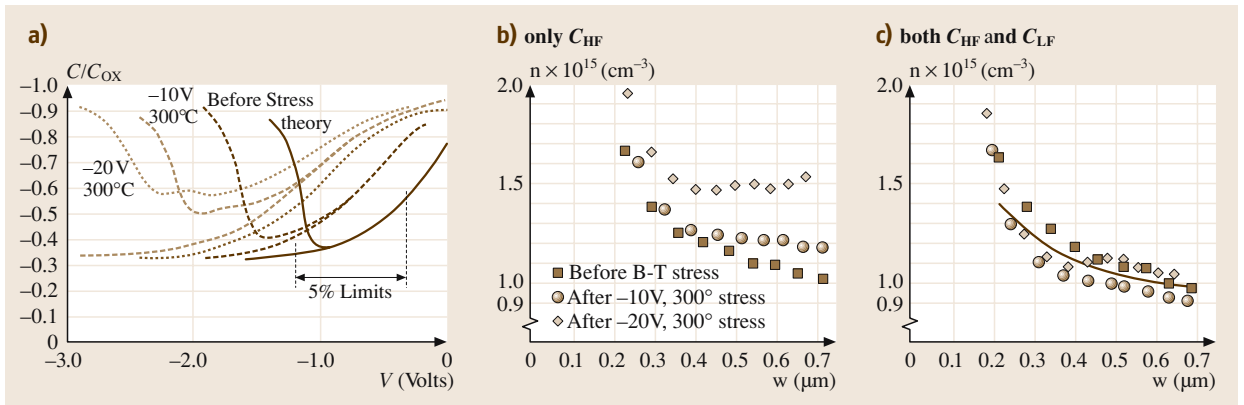

Fig. 20.20a–c C – V curves and doping profiles of a MOS structure with 145 nm oxide and uniform doping of 10^{15} cm^{-3} before and after bias temperature stress [20.32]. (a) Theoretical and (stretched) measured C – V curves. (b) Doping profile deduced from only C_{HF} (see (20.57)); (c) Doping profile deduced from both C_{HF} and C_{LF} (see (20.59)). After [20.32]

The doping profile obtained in this way is reliable for depths w of between $3\lambda_{\text{Debye}}$ and $w_{\text{max}}/2$, when the MOS structure is in depletion and weak inversion, but not in accumulation. That is, $C_{\text{LF}} < 0.7C_{\text{OX}}$ as a simple rule. As illustrated in Fig. 20.21, the range of w values between $3\lambda_{\text{Debye}}$ and equilibrium, obtained via quasi-static C - V measurements, cover about half-a-decade. With proper corrections, the lower distance decreases to one Debye length [20.30]. Using nonequilibrium (transient) C - V measurements in deep depletion, the profiling can be extended to higher distances by about an order of magnitude, but further limitations can appear due to the high-frequency response of the interface charge, measurement errors, avalanche breakdown in deep depletion, or charge tunneling in highly doped substrates and thin oxides. More details are presented in [20.29].

20.3.3 Density of Interface States

Interface traps change their charge state depending on whether they are filled or empty. Because interface trap occupancy varies with the slow gate bias, stretching of the C - V curves occurs, as illustrated in Fig. 20.20. A quantitative treatment of this “stretch-out” can be obtained from Gauss’ law as

$$C_{\text{OX}}(V_G - \psi_S) = -Q_S - Q_{\text{IT}} = -Q_T, \quad (20.61)$$

where Q_S and Q_{IT} are the surface and interface trap charges (per unit area), which are both dependent on the surface band-bending ψ_S , $Q_T = Q_S + Q_{\text{IT}}$ is the total charge in the MOS structure, C_{OX} is the gate capacitance (per unit area), and V_G is the bias applied at the gate of the MOS structure. For simplicity, the (gate metal)-to-(semiconductor bulk) potential ψ_{MS} is omitted in (20.61), but in a real structure the constant ψ_{MS} must be subtracted from V_G . As follows from (20.61), small changes ∂V_G in gate bias cause changes $\partial \psi_S$ in the surface potential bending, and the surface C_S and interface trap C_{IT} capacitances (both per unit area) can represent Q_S and Q_{IT} , given by

$$C_{\text{OX}}\partial V_G = (C_{\text{OX}} + C_S + C_{\text{IT}}) \cdot \partial \psi_S. \quad (20.62)$$

C_S and C_{IT} are in parallel and in series with the C_{OX} , respectively. Therefore, the measured low-frequency capacitance C_{LF} (per unit area) of the MOS structure becomes

$$\begin{aligned} C_{\text{LF}} &= \frac{\partial Q_T}{\partial V_G} = \frac{\partial Q_T}{\partial \psi_S} \cdot \frac{\partial \psi_S}{\partial V_G} \\ &= \frac{C_{\text{OX}}(C_S + C_{\text{IT}})}{C_{\text{OX}} + C_S + C_{\text{IT}}}. \end{aligned} \quad (20.63)$$

Equation (20.63) shows that stretch-out in the C - V curve can arise due to a non-zero value of C_{IT} , which deviates from the ideal case of $C_{\text{IT}} = 0$.

According to [20.29] (p. 142), D_{IT} is the density of interface states per unit area (cm^2) and per unit energy (1 eV) in units of $\text{cm}^{-2}\text{eV}^{-1}$. Since the occupancy of the interface states has a Fermi–Dirac distribution, then upon integrating over the silicon band-gap, the relation between C_{IT} and D_{IT} is

$$C_{\text{IT}}(\psi_S) = qD_{\text{IT}}(\phi_B + \psi_S), \quad (20.64)$$

where $\phi_B = (k_B T/q) \ln(n/n_i)$ is the shift of the Fermi level from the intrinsic level $\phi_i = (E_c - E_v)/2q$ in the silicon bulk of the MOS structure due to the doping concentration n , and n_i is the thermally generated carrier concentration in silicon. Since the derivative of the Fermi–Dirac distribution is a sharply peaking function, then $C_{\text{IT}}(\psi_S)$ at particular ψ_S probes $D_{\text{IT}}(\phi_B + \psi_S)$ over a narrow energy range of $k_B T/q$, in which D_{IT} can be assumed to be constant and zero outside this interval. Thus, varying the gate bias V_G , and therefore ψ_S , (20.64) can be used to obtain the density of states D_{IT} at a particular energy shift $q(\phi_B + \psi_S)$ from the silicon intrinsic (mid-gap) energy E_i .

It is evident from (20.63) and (20.64) that the experimental values for D_{IT} can be obtained only when C_{IT} , and ψ_S are determined from C - V measurements. The simplest way to determine ϕ_B is to get the average doping density n using the maximum–minimum high-frequency capacitance method (see (20.52) and Fig. 20.18), or to use the values of n from doping profiles at $0.9w_{\text{max}}$ - see (20.58) [20.30]. Either the high-frequency or the low-frequency C - V measurement can be used to obtain C_{IT} , but it is necessary to calculate C_S as function of ψ_S , which makes it difficult to process the experimental data.

The most suitable technique for experimentally determining D_{IT} is the combined high–low frequency capacitance method ([20.29], Sect. 8.2.4, p. 332). The interface traps respond to the measurement of low–frequency capacitance C_{LF} , whereas they do not respond to the measurement of the high-frequency measurement C_{HF} . Therefore, C_{IT} can be obtained from measurements by “subtracting” C_{HF} from C_{LF} , given by

$$\begin{aligned} C_{\text{IT}} &= \left(\frac{1}{C_{\text{LF}}} - \frac{1}{C_{\text{OX}}} \right)^{-1} \\ &\quad - \left(\frac{1}{C_{\text{HF}}} + \frac{1}{C_{\text{OX}}} \right)^{-1}. \end{aligned} \quad (20.65)$$

Denoting $\Delta C = C_{\text{LF}} - C_{\text{HF}}$, the substitution of (20.65) into (20.64) provides a direct estimate of D_{IT} from C - V

measurements (see also [20.3], p. 371) as

$$D_{IT} = \frac{\Delta C}{q} \left(1 - \frac{C_{LF}}{C_{OX}}\right)^{-1} \left(1 - \frac{C_{HF}}{C_{OX}}\right)^{-1} \quad (20.66)$$

Note that the combined high–low frequency capacitance method provides C_{IT} and D_{IT} as function of gate bias V_G . However, if D_{IT} needs to be plotted as a function of the position in the energy band-gap, the surface band-bending ψ_S must also be determined as function of gate bias V_G , as follows from (20.64).

There are several ways to obtain the relation between ψ_S and V_G . One way is to create a theoretical plot of C_{HF} versus ψ_S and then, for any choice of C_{HF} , a pair of values for ψ_S and V_G is found (see [20.29] p. 327). This method is relatively simple if the doping concentration n in the silicon is uniform and known, because the high-frequency silicon surface capacitance C_S under depletion and accumulation is a simple function of the band-bending ψ_S , and the flat-band capacitance C_{FB} ([20.29] pp. 84, 97, 164) is given by

$$C_{FB} = \frac{\varepsilon_{Si}}{\lambda_{Debye}} = \sqrt{\frac{\varepsilon_{Si} q^2 n}{k_B T}} \quad (20.67)$$

$$C_S(\psi_S) \approx \begin{cases} \frac{C_{FB}}{\sqrt{2}} \frac{\exp\left(\frac{q\psi_S}{k_B T}\right) - 1}{\sqrt{\exp\left(\frac{q\psi_S}{k_B T}\right) - \frac{q\psi_S}{k_B T} - 1}}, & \psi_S > 0 \text{ in accumulation} \\ C_{FB}, \psi_S = 0 \text{ at flat band,} \\ \frac{C_{FB}}{\sqrt{2}} \frac{1 - \exp\left(\frac{q\psi_S}{k_B T}\right)}{\sqrt{\exp\left(\frac{q\psi_S}{k_B T}\right) - \frac{q\psi_S}{k_B T} - 1}}, & \psi_S < 0 \text{ in depletion.} \end{cases} \quad (20.68)$$

Since C_S is in series with C_{OX} , then the theoretical C_{HF} is obtained as a function of the band-bending ψ_S by

$$\frac{1}{C_{HF}(\psi_S)} = \frac{1}{C_{OX}} + \frac{1}{C_S(\psi_S)} \quad (20.69)$$

For a uniformly doped silicon with SiO_2 as the insulator, the ratio $C_{HF}(V_{FB})/C_{OX}$ at gate bias for flat-band conditions is given ([20.3], p. 349) by

$$\frac{C_{HF}(V_{FB} \text{ or } \psi_S = 0)}{C_{OX}} = \frac{1}{1 + \frac{136\sqrt{T/300}}{t_{ox}\sqrt{n}}}, \quad (20.70)$$

where t_{ox} is the oxide thickness (cm), n is the doping (cm^{-3}), and the T is the temperature (K).

It was demonstrated in [20.29] that the method of using a theoretical plot to obtain the relation between ψ_S and V_G works well in the case of uniformly doped silicon even if only high-frequency C – V measurements are used to obtain the density of states; that is, the $1/C_{HF}^2$ versus V_G plot is almost a straight line. However, with substrates that are not uniformly doped, the method is inconvenient because the corrections in (20.67) and (20.68) are difficult to implement. Therefore, in practice, a method based on low-frequency C – V measurement is preferred [20.30].

Low-frequency C – V measurement was first used to obtain the relation between ψ_S and V_G [20.34]. This method is based on the integration of (20.65) from an initial gate bias V_{G0} , arbitrarily chosen either under strong accumulation or strong inversion, to the desired V_G at which the band-bending $\psi_S(V_G)$ is to be obtained. Since C_{IT} is part of (20.65), then the low-frequency C – V curve ([20.29] p. 93) is integrated as

$$\psi_S(V_G) = \psi_{S0} + \int_{V_{G0}}^{V_G} \left(1 + \frac{C_{LF}(V_G)}{C_{OX}}\right) dV_G. \quad (20.71)$$

The value of ψ_{S0} is selected such that $\psi_S(V_{FB}) = 0$ when integrating from V_{G0} to the flat-band gate voltage V_{FB} . In this case, V_{FB} is usually obtained beforehand from the point of V -intercept with $1/C_{OX}^2$ when extrapolating

Fig. 20.22a,b Results from the combined high–low frequency capacitance method [20.33]. (a) High-frequency C – V curve; (b) low-frequency C – V curve. The energy profile for the density of interface states D_{IT} is shown in the inset, as calculated by (20.64), (20.66) and (20.71)

Fig. 20.23 Energy ranges in the silicon band-gap of a p-type substrate over which the density of interface traps can be determined using various measurement methods and characterization techniques. (After [20.3], p. 104)

the linear part of the $1/C_{\text{HF}}^2$ versus V_G curve toward the V_G axis (Fig. 20.19). After determining ψ_{S0} , (20.71) provides the relation between ψ_S and V_G . Thus, the density of states D_{IT} obtained from (20.66) as function of V_G using the combined high–low frequency capacitance method can be plotted against the position of D_{IT} in the silicon band gap, as given by (20.64). High and low frequency $C-V$ measurements can therefore be used to plot the data, as illustrated in the insert of Fig. 20.22.

20.4 Current–Voltage Measurements

20.4.1 $I-V$ Measurements on a Simple Diode

Current–voltage measurements of mainstream semiconductor devices are perhaps the simplest and most routine measurements performed, and they can provide valuable information about the quality of materials used. For example, if we consider the $I-V$ characteristics of a p–n diode structure, the source–substrate or drain–substrate junctions can provide useful information on the quality of the junction, such as whether defects are present (they give rise to generation–recombination currents or large parasitic resistances for the contacts at the source, drain or substrate terminals). This is easily seen from the current–voltage relation given by the sum of the diffusion (I_{DIFF}) and recombination (I_{GR}) currents:

$$I_D = I_{\text{DIFF}} + I_{\text{GR}} = I_{D0} \left[\exp \left(\frac{eV_D}{nk_B T} \right) - 1 \right] + I_{\text{GR0}} \cdot \exp \left(\frac{eV_D}{2k_B T} \right) \quad (20.72)$$

Overall, many different techniques are used to determine the density of states D_{IT} (please see Fig. 20.13). For some of these techniques, the ability to sense the energy position of D_{IT} in the band-gap of silicon is summarized in [20.3]. Most of them use $C-V$ measurements, but others are based on $I-V$ measurements taken during the subthreshold operation of MOS transistors, deep-level transient spectroscopy (DLTS), charge pumping (CP) in a three-terminal MOS structure, cryogenic temperature measurements, and so on. Each technique has its strengths and weaknesses, which are discussed in [20.3, 35].

In the methods discussed above, it has been assumed that the gate bias V_G varies slowly with time, 20–50 mV/s, and that the MOS structure is in equilibrium; that is, the minority carriers are generated and the inversion layer is readily formed in the MOS structure when V_G is above the threshold. However, the time constant for minority carrier generation is high in silicon (≈ 0.1 s or more), and it is possible to use nonequilibrium high-frequency $C-V$ measurements to further analyze the properties of the MOS structure. Some applications of these methods are presented later.

where I_{D0} and I_{GR0} are the zero-bias diffusion and recombination currents respectively, n is an ideality factor (typically 1), and V_D is the voltage across the intrinsic diode, which is given by

$$V_D = V_{\text{applied}} - I_D R_{\text{parasitic}}. \quad (20.73)$$

For (20.72), a plot of $\ln(I_D)$ versus V_D allows us to separate out the diffusion and the recombination current components. From (20.72) and (20.73), we can also use the diode's $I-V$ characteristics to determine the parasitic resistance in series with the intrinsic diode, as described in detail in [20.36]. In most cases, this $R_{\text{parasitic}}$ is dominated by the contact resistance.

20.4.2 $I-V$ Measurements on a Simple MOSFET

Simple current–voltage measurements – drain current versus gate voltage ($I_{\text{DS}} - V_{\text{GS}}$), and I_{DS} versus drain voltage (V_{DS}) – are routinely taken on MOSFETs in order to study their electrical characteristics; however, these can also be used to obtain useful information

Fig. 20.24 Typical subthreshold characteristics of a MOS-FET. The interface state density can be extracted from S

on the quality of the semiconductor, contacts, oxide and semiconductor–oxide interface. For example, the $I_{DS} - V_{GS}$ characteristics at very small V_{DS} biases (linear region of operation) for a set of test transistors of fixed channel width and different channel lengths is often used to extract parameters such as the threshold voltage (V_T), the transconductance (g_m), the intrinsic mobility (μ_0) and the mobility degradation coefficients θ_0 and η , the parasitic source (R_S) and the drain resistances (R_D) in series with the intrinsic channel, the channel length reduction ΔL , the output conductance (g_{DS}) and the subthreshold slope (S) [20.37].

These parameters are required for modeling and they directly impact the device's performance. However, some of these parameters can also be used to assess the quality of the silicon–silicon dioxide (Si–SiO₂) interface [20.38, 39]. For example, interface states at the Si–SiO₂ interface can change the threshold voltage, the subthreshold slope and the mobility, all of which will impact on the drain–source (I_{DS}) current flowing through the device. Here, we look at one parameter in more detail – the subthreshold slope S in mV (of V_{GS})/decade (of I_{DS}).

First, the interface trap density (D_{IT}) can be determined from a semi-log plot of $I_{DS} - V_{GS}$ characteristics at very low drain biases, as shown in Fig. 20.24. We start with the expression for the subthreshold slope

$$S = \frac{k_B T}{q} \ln(10) \left(1 + \frac{C_D + C_{IT}}{C_{OX}} \right) \quad (20.74)$$

in which

$$C_D = \frac{q \epsilon_{Si} N_A}{\sqrt{2\psi + |V_B| - k_B T/q}} \quad (20.75)$$

D_{IT} can then be calculated from

$$C_{IT} = q D_{IT} \quad (20.76)$$

once C_{IT} is determined from (20.74). In fact, a recent comparison in [20.40] of the interface trap densities extracted from capacitance, subthreshold and charge pumping measurements produced similar results, demonstrating that simple and fast $I-V$ measurements based on the subthreshold technique can provide useful information on the Si–SiO₂ quality.

20.4.3 Floating Gate Measurements

The floating gate technique is another simple $I-V$ measurement in which the evolution of the drain current I_{DS} is monitored after the gate bias has been removed. It has been shown to be particularly useful when monitoring early-mode hot-carrier activity in MOS transistors [20.40, 41]. In this measurement, we first check the oxide quality by biasing the transistor in the strong linear region (very low V_{DS} and a V_{GS} well above V_T), and then lift the gate voltage probe so that $V_{GS} = 0$ V and measure the evolution of I_{DS} with time. For a high-quality gate and spacer oxide, I_{DS} remains constant for a long time, indicating that there is negligible carrier injection across the gate oxide through Fowler–Nordheim tunneling or other leakage mechanisms.

A second precaution is to have a dry or inert gas such as nitrogen flowing over the chip to reduce the possibility of other leakage mechanisms such as that from water vapor. The measurement set-up for this experiment is shown in Fig. 20.25. The

Fig. 20.25 Schematic diagram showing the set-up used for floating gate measurements. The area where charge is trapped after hot electrons are applied is shown

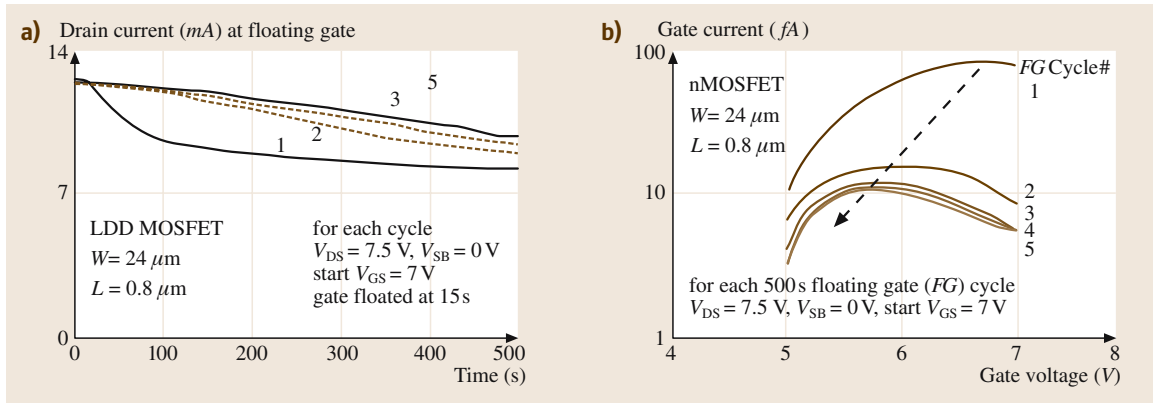

Fig. 20.26 (a) Evolution of the drain current over five floating gate cycles. Biasing conditions were chosen to maximize hot-electron gate currents. Note that the maximum drop in drain current occurs after the first floating gate cycle. (b) Extracted gate currents using (20.77) and the measurements in (a). As with the drain current, the maximum change in gate current occurs between floating gate cycles 1 and 2. The shift in the peak of the gate current is explained in [20.38,41].

evolution of the floating gate current over several cycles with the gate voltage applied and then removed is shown in Fig. 20.26. The biasing voltages and time at which the gate is floated are also given in Fig. 20.26a. For this experiment, a biasing condition of $V_{GS} \approx V_{DS}$ was chosen for a high-impact ionization-induced gate current, but a lower-than-maximum electron injection situation was used for the initial biasing condition.

From the evolution of I_{DS} and the $I_{DS} - V_{GS}$ characteristics of a virgin (not intentionally stressed) transistor at the same V_{DS} as the floating gate measurements, and from measurements of the total capacitance associated with the gate (C_G), the gate current (I_G) evolution after each floating gate cycle can be deter-

mined using

$$I(V_{GS}) = C_G \frac{dV_{GS}}{dt} \quad (20.77)$$

This $I_G - V_{GS}$ evolution is shown in Fig. 20.26b. An ancillary benefit of the floating gate technique is that very small gate currents (in the fA range or even smaller) can be easily determined by measuring much larger drain currents using, for example, a semiconductor parameter analyzer. The reason for this is that the gate current is not directly measured in this technique – it is determined from $I_{DS} - V_{GS}$ and (20.77). Also, the change in the floating gate current after the first few cycles can be used to monitor for early mode failure after statistical evaluation.

20.5 Charge Pumping

Charge pumping (CP) is another electrical technique that is well suited to studying semiconductor–insulator interfaces in MOSFETs [20.42–47]. There are several versions of the CP technique: spatial profiling CP [20.43–47], energy profiling CP [20.48], and, more recently, new CP techniques [20.49] that permit the determination of both interface states (N_{IT}) and oxide traps (N_{OT}) away from the interface and inside the oxide. The charge pumping technique is more complicated than either of the $I-V$ or floating gate methods. However, it is a very powerful technique for assessing interface quality and it works well even with very small transistor geome-

tries and very thin gate oxides, where tunneling can be a problem.

The charge pumping technique was first used in 1969 [20.50] to measure the interface traps at Si–SiO₂ interface. Since then, there have been numerous publications with enhancements, refinements and applications of the technique to a variety of semiconductor–insulator interfacial studies. In the basic charge pumping experiment, the gate of an NMOST (for example) is pulsed from a low value (V_L) when the device is in accumulation to a high value (V_H) when the device is in inversion. This results in the filling of traps between

Fig. 20.27 Example of spatial profiling charge-pumping set-up used when the source and drain biases are slightly different

Fig. 20.28 Demonstration of how the CP curve is generated by varying the base level of the pulse so that the entire pulse is between V_{FB} and V_T

$E_{F,ACC}$ (corresponding to V_L) and $E_{F,INV}$ (corresponding to V_H) with holes and electrons, respectively. When pulsing the gate between accumulation at V_L and inversion at V_H , a current flows due to the repetitive recombination at the interface traps of minority carriers from the source and drain junctions with majority carriers from the substrate. This current is termed the charge pumping current, and it was found to be proportional to the frequency of the gate pulse, the gate area and the interface state density. Its sensitivity is better than $10^9 \text{ cm}^{-2} \text{ eV}^{-1}$. In the traditional CP experiment

Fig. 20.29 Spatial interface state distribution over the channel in a $1 \mu\text{m}$ -long device. The stress was applied for 2 h at $V_{DS} = 5 \text{ V}$ and $V_{GS} = 2.4 \text{ V}$

shown in Fig. 20.27, but with $\Delta V_S = |V_D - V_S| = 0 \text{ V}$, the gate G is connected to a pulse generator, a reverse bias V_R or no bias is applied to both sources S and drain D terminals, and the charge pumping current flowing in the substrate terminal, I_{CP} , is measured. To generate a typical charge pumping curve (as shown in the top part of Fig. 20.28), the base level of the pulse is varied, taking the transistor from below flat-band to above surface inversion conditions, as shown in the bottom part of Fig. 20.28.

In the traditional CP experiment, the charge pumping current I_{CP} is given by

$$I_{CP} = q A_{GATE} \overline{D_{IT}} \Delta E, \quad (20.78)$$

where

$$\Delta E = (E_{F,INV} - E_{F,ACC}). \quad (20.79)$$

This expression assumes that the electrical and physical channel lengths are the same. However, for short channel devices, this assumption results in an error. Therefore, a more accurate expression is

$$I_{CP} = q f W \int_{x_s}^{x_d} N_{IT}(x) \cdot (q \Delta \psi_{SO}) \quad (20.80)$$

$$x_d = L - \sqrt{\frac{2\epsilon_{Si}}{qN}} (\sqrt{V_D + \psi_S} - \sqrt{\psi_S}). \quad (20.81)$$

The interface state density at the edge of the drain depletion region [$N_{IT}(x_d)$] is given by

$$N_{IT}(x_d) = \frac{1}{qfWq\Delta\psi_{s0}} \left(\frac{dx_s}{dV_S} \right)^{-1} \cdot \left(\frac{dI_{CP}}{dV_S} \right)_{V_D=\text{constant}} \quad (20.82)$$

When performing spatial profiling CP experiments, some precautions are required. The first is that a voltage difference ΔV_S between V_D and V_S that is too small results in a difference in I_{CP} that is too small as well, and hence a large error in $N_{IT}(x)$, as indicated from (20.82).

On the other hand, values of ΔV_S that are too large result in a I_D that is too high and hence more substrate current I_B . This current I_B can interfere with I_{CP} if ΔV_S is large or if L is very short, resulting in a large error in $N_{IT}(x)$. The range 50–100 mV for ΔV_S seems to be a good compromise for the devices investigated in [20.43, 44]. Experimental results for spatial profiling CP measurements indicate that $N_{IT}(x)$ peaks near S/D edges. However, after normal mode stress, $N_{IT}(x)$ only increases near D. This is shown in Fig. 20.29. More details about charge pumping can be found in a recent review [20.51].

20.6 Low-Frequency Noise

20.6.1 Introduction

Low-frequency noise (LFN) spectroscopy requires very good experimental skills in the use of low-noise instrumentation as well as grounding and shielding techniques. Other special considerations are also required, which are discussed later. Although it is time-consuming to perform, it has been widely used to probe micro-

scopic electrical transport in semiconductors and metals. LFN is very sensitive to defects in materials and devices, and large differences in LFN characteristics can be observed in devices with identical electrical current–voltage characteristics. This is mainly because electrical I – V measurements only probe the average or macroscopic transport in devices and so are not as sensitive to defects as LFN. Due to its sensitivity to defects, traps or generation–recombination centers, LFN has been proposed as a good tool for predicting device reliability. For example, LFN has been used to predict the reliabilities of metal films [20.52], and has been used in processing steps that produce photodetectors with better performance [20.53, 54]. LFN noise is sensitive to both bulk and surface defects or contaminants of a material.

Using low-frequency noise spectroscopy and biasing the transistor in saturation, we can spatially profile the defect density near the drain and source terminals for devices in normal and reverse modes of operation [20.55]. Low-frequency noise in the linear region also allows us to extract the average defect density over the entire channel region at the silicon–silicon dioxide interface [20.56, 57]. Noise experiments were performed on small-geometry polysilicon emitter bipolar transistors to investigate the number of interface states in the thin interfacial oxide layer between the monocrystalline and polycrystalline silicon [20.58–68]. Recent experiments using body or substrate bias (V_B) in a MOS transistor allowed us to look at the contribution of bulk defects (defects away from the silicon–silicon dioxide interface) and their contribution to device noise [20.69–71]. This is important since substrate biasing has been proposed as a means to cleverly manage power dissipation and speed in emerging circuits and systems [20.72].

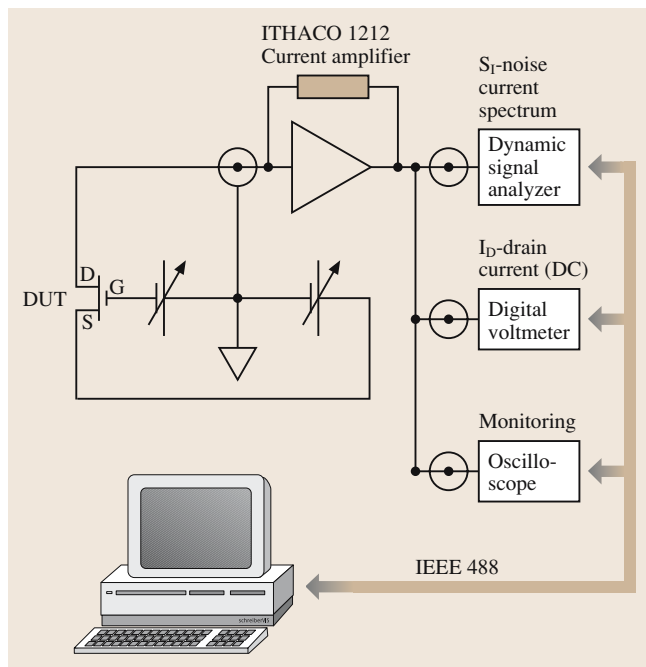

Fig. 20.30 System for measuring low-frequency noise. In this diagram, the device under test is any field-effect or thin-film transistor

Fig. 20.31 Schematic representation of a “large”-area PE-BJT with many traps distributed uniformly across the band gap and the emitter area, and with a $g(\tau) = 1/\tau$ distribution for the time constant. The resulting spectrum is $1/f$ noise

We will discuss how low-frequency noise (LFN) spectroscopy can be applied to the interfacial oxide layer between the mono-silicon and polysilicon emitter in bipolar junction transistors (BJTs) here. The experimental system shown in Fig. 20.30 is used for LFN measurements of FETs; the same system can also be used for BJTs.

As mentioned before, special attention must be paid to grounding and shielding in LFN measurements, as this is crucial to minimizing the effects of experimental and environmental noise sources on the device under test (DUT). Because electric power supplies are noisy, especially at 60 Hz (in North America) and its harmonics, and this noise can dominate the noise of the DUT, batteries are often used to supply the voltage. Metal film resistors are the preferred means of changing the biasing conditions, because of their better low-noise characteristics compared to carbon resistors, for example.

With these experimental precautions taken, the noise signal from the transistor might still be too low to be directly measured using a spectrum or signal analyzer.

Therefore, a low-noise voltage or current amplifier, whose input noise sources are lower than that of the noise signal, is used to boost the noise signal. In addition, other instruments might be used to measure currents or voltages, or to display the waveforms (as shown in Fig. 20.30). An example of a low-frequency noise characterization system that we have used to study the noise in thin film polymer transistors is shown in Fig. 20.30. Note that LFN measurements are time intensive because a large number of averages are required for smooth spectra. Also, in noise measurements, the power spectrum densities S_V and S_I for the noise voltages and currents are measured, in units V^2/Hz and I^2/Hz , respectively.

20.6.2 Noise from the Interfacial Oxide Layer

Here we present some sample results and show how low-frequency noise spectra in ultrasmall devices can be used to estimate the oxide trap density. Generally, the low-

Fig. 20.32 Schematic representation of a “medium”-area PE-BJT ($\approx 0.5 \mu\text{m}^2$) with a few traps. Note that g - r bumps appear for each trap since there are only a few traps

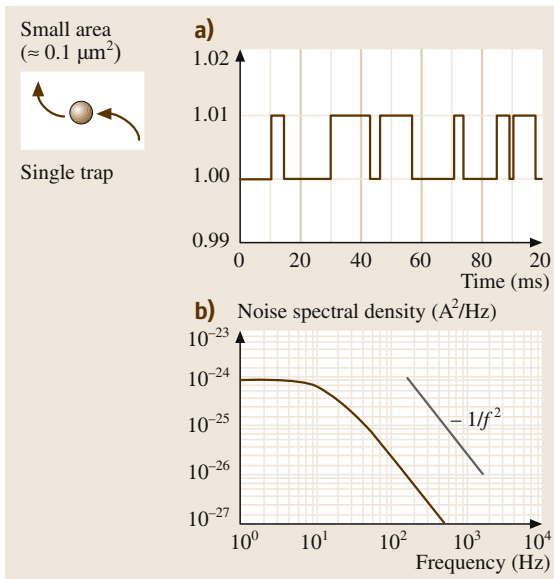

Fig. 20.33 Schematic representation of a “small”-area PE-BJT ($\approx 0.1 \mu\text{m}^2$) with one trap. Note that a single RTS and g-r spectrum appear because there is only one trap

base current, the noise spectra can be modeled as

$$S_{I_B} = \frac{K_F \cdot I_B^{A_F}}{f} + \sum_{i=1}^n \frac{B_i \tau_i}{1 + (2\pi f \tau_i)^2} + 2qI_B, \quad (20.83)$$

where the symbols have their usual meanings, see [20.68] for example.

As described in [20.63–68], the LFN in PE BJT originates from the thin layer of oxide between the monocrystalline and polycrystalline silicon emitter. The defects at this interface may be dangling oxygen bonds, oxygen vacancies, interface states or oxide traps [20.63]. Devices with large emitter areas have many traps, and these produce generation–recombination noise which produce $1/f$ noise when added. This is schematically shown in Fig. 20.31.

As the device area is reduced, and assuming a constant trap density (which is normally true for devices on the same wafer), then there are fewer traps in the interfacial oxide layer for smaller area devices. In this case, the spectral density of the noise changes and it gains characteristic “bumps” associated with resolvable g-r noise components. This is schematically shown in Fig. 20.32.

In very small devices with only a single trap, for example, the noise spectrum changes dramatically; only g-r noise is observed in the frequency domain along with a random telegraph signal (RTS) in the time domain. This is schematically shown in Fig. 20.33. Real experimental results are shown for three sizes of transistors (2.4 , 0.64 and $0.16 \mu\text{m}^2$) in Fig. 20.34. Here, one can see how $1/f$ noise is made up of g-r spectra as the emitter geometries are scaled to smaller and smaller values. For the PE BJT with an emitter area of $0.16 \mu\text{m}^2$, a lower bound of $\approx 10^9/\text{cm}^2$ can be approximated for the oxide trap density. Similar results have been obtained for MOSFETs [20.73].

20.6.3 Impedance Considerations During Noise Measurement

Two basic circuits can be employed when measuring the low-frequency noise (LFN) in a device. These configurations are sketched in Fig. 20.35. In voltage noise measurement (Fig. 20.35a), a low-noise preamplifier senses the voltage across the device, and this signal is sent to a spectrum analyzer or a fast Fourier transform (FFT) analyzer. In current noise measurements (Fig. 20.35b), the low-noise preamplifier senses the current through the device, converts it into a voltage, and forwards the voltage to a FFT or spectrum analyzer.

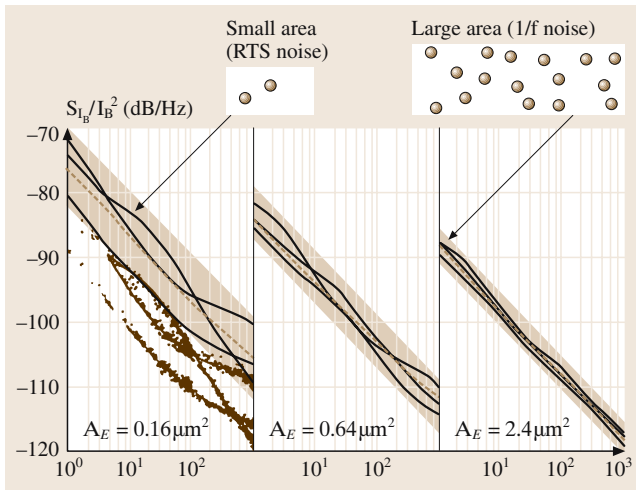

Fig. 20.34 Experimental results for low-frequency noise spectra from sets of large-, medium- and small-area PE-BJTs. In all cases, the average spectrum is $1/f$ noise and the relative magnitude of the $1/f$ noise is the same; that is, the area of $K_F \times$ is the same for the three sets of transistors. After [20.59–62]

frequency noise spectra of polysilicon emitter (PE) BJTs are made up of $1/f$ noise, generation–recombination (g-r) noise and shot noise sources. In the case of the

In principle, both configurations can be used for LFN measurement, but the impact of the nonideality of the amplifier (such as the input impedance, noise voltage and current) changes when the device impedance changes. Also, the noise from the bias source varies with each measurement set-up.

The noise equivalent circuit used for voltage measurement is shown in Fig. 20.36. The noise from the amplifier is represented by the input-referred noise voltage (S_{Vn}) and noise current (S_{In}) sources. The noise voltage from the bias is represented by S_{V0} . The impedance of the bias source is R_0 , whereas the input impedance of the amplifier is neglected, since it is usually very high compared to R_0 . The impedance of DUT is r_d . The noise current S_{Id} of the device that can be measured, assuming that the noise voltage at the input of the amplifier $S_{Vm} = S_{Id} \times r_d^2$. However, the amplifier sees a different level of S_{Vm} , given by

$$S_{Vm} = \frac{S_{OUT}}{A^2} = S_{V0} \left(\frac{r_d}{r_d + R_0} \right)^2 + S_{Vn} + (S_{In} + S_{Id})Z^2 \quad (20.84)$$

where

$$Z = (r_d // R_0) = \frac{r_d \cdot R_0}{r_d + R_0} \quad (20.85)$$

and A is the voltage gain of the amplifier. Therefore, the estimated value for S_{Id} is

$$S_{Id} = \frac{S_{Vm} - S_{Vn}}{Z^2} - \frac{S_{V0}}{R_0^2} - S_{In}. \quad (20.86)$$

The uncertainty in (20.86) is

$$\frac{\Delta S_{Id}}{S_{Id}} = \frac{\Delta S_{Vn}}{S_{Vm}} + \frac{\Delta S_{V0}}{S_{Vm}} \left(\frac{Z}{R_0} \right)^2 + \frac{\Delta S_{In}}{S_{Vm}} Z^2 \quad (20.87)$$

where $\Delta S \leq S$ denotes the uncertainty in each noise source. As seen from (20.87), the impact of the bias source noise ΔS_{V0} and the input current noise ΔS_{In} can be reduced if the impedance of the measurement circuit Z is low and the ratio r_d/R_0 is kept much less than 1; in other words, the voltage noise measurement is more appropriate for low-impedance devices, such as diodes at forward biasing, and the noise floor of the measurement is limited by the input-referred voltage noise S_{Vn} of the amplifier.

For the other (dual) case, current noise measurement, the noise equivalent circuit is shown in Fig. 20.37. The corresponding equations for the measured noise current S_{Im} , Z , the device noise S_{Id} , and the uncertainty,

Fig. 20.35a,b Basic circuits used to measure the low-frequency noise (LFN) in a device (DUT). (a) Voltage noise measurement; (b) current noise measurement

respectively, are given by (20.88–20.91) below

$$S_{Im} = \frac{S_{OUT}}{R^2} = \frac{S_{V0}}{(r_d + R_0)^2} S_{In} + \frac{S_{Vn}}{Z^2} + S_{Id} \left(\frac{r_d}{r_d + R_0} \right)^2 \quad (20.88)$$

$$Z = (r_d + R_0) // R = \left(\frac{1}{R} + \frac{1}{r_d + R_0} \right)^{-1} \quad (20.89)$$

$$S_{Id} = (S_{Im} - S_{In}) \left(1 + \frac{R_0}{r_d} \right)^2 - \frac{S_{V0}}{r_d^2} - \frac{S_{Vn}}{Z^2} \left(1 + \frac{R_0}{r_d} \right)^2 \quad (20.90)$$

$$\frac{\Delta S_{Id}}{S_{Id}} = \frac{\Delta S_{In}}{S_{Im}} + \frac{\Delta S_{V0}}{S_{Im}} \frac{1}{(r_d + R_0)^2} + \frac{\Delta S_{Vn}}{Z^2 S_{Im}} \quad (20.91)$$

As expected from duality, it is apparent from (20.91) that the impact of the bias source noise ΔS_{V0} and the input

Fig. 20.36 Noise equivalent circuit for voltage noise measurements

Fig. 20.37 Noise equivalent circuit of the current noise measurement

voltage noise ΔS_{In} can be reduced if the impedance of the measurement circuit Z and $(r_d + R_0)$ are both high; in other words, the *current noise measurement is more appropriate for high-impedance devices, such as diodes at reverse biasing*, and the noise floor of the measurement is limited by the input-referred current noise S_{I_n} of the amplifier.

This analysis above demonstrates that the choice of the measurement configuration follows our expectation that voltage should be measured in low-impedance devices and current in high-impedance devices. Also, the noise floor limiting parameter of the preamplifier is of the same type as the type of measurement;

that is, input-referred noise voltage for voltage noise measurement and input-referred noise current for current noise measurement. Note that there is a trade-off between the voltage and current noise in amplifiers, which implies that the measurement configuration – either voltage or current measurement – should also be carefully selected with respect to the impedance of the device under test. In addition, four-point connection can be used to measure the noise in very low impedance devices ($r_d < 100$). These and other considerations for low-frequency noise instrumentation are discussed in many papers, for example [20.74–76].

20.7 Deep-Level Transient Spectroscopy

Deep-level transient spectroscopy (DLTS) is a fairly complicated electrical characterization technique where the temperature is varied in large range from cryogenic temperatures (< 80 K) to well above room temperature (> 400 K). However, it is a powerful and versatile technique for investigating deep-level defects and it also gives accurate values for the capture cross-sections of defects. There are several DLTS techniques and [20.77, 78] provide recent reviews of the subject. In DLTS, the semiconductor device or junction is pulsed with an appropriate signal, and the resulting transient (such as capacitance, voltage or current) is monitored at different temperatures. Using these recorded transients at different temperatures, it is possible to generate a spectrum with peaks, each of which is associated with a deep level. The heights of the peaks are proportional to the defect density.

Here, we will focus on a new version of DLTS: the constant resistance (CR) DLTS technique [20.79–81]. We were able to accurately investigate bulk defects in a variety of test structures with CR-DLTS. Using body bias in a MOS transistor, we were able to distinguish interfacial and bulk defects that are important for different applications. For example, interfacial defects are important for electronic applications, and bulk defects are important for imaging or radiation detection applications. Examples of results from DLTS studies with and without body bias will be discussed.

CR-DLTS is well-suited to investigations of electrically active point defects that are responsible for the

Fig. 20.38 Schematic representation of a conventional DLTS system. The time scans from which the DLTS temperature spectrum is obtained are shown on the right

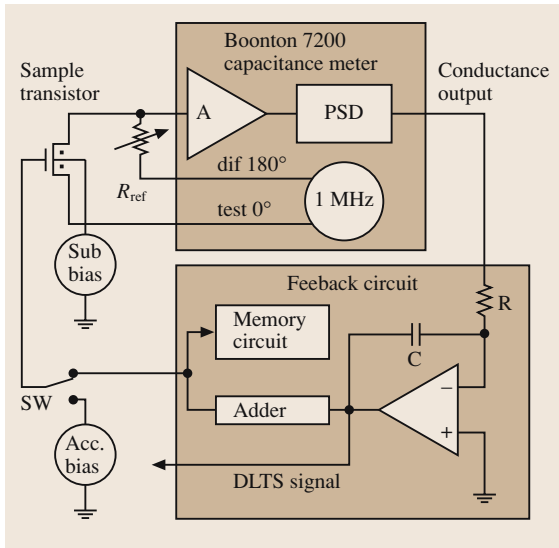

Fig. 20.39 Block diagram representation of the CR-DLTS system

creation of deep levels in the semiconductor band-gap. CR-DLTS can also be used to distinguish bulk traps and interface traps in MOSFETs.

A conventional DLTS system is shown schematically in Fig. 20.38. In DLTS, an excitation pulse is applied to the sample to fill all of the traps and then the pulsing is stopped. The next step is to detect the transient signal from the sample due to charge emission from the traps. The right side of Fig. 20.38 shows capacitance transients at eight different temperatures. By selecting a time window from t_1 to t_2 , and then plotting $[C(t_1) - C(t_2)]$ as a function of temperature, a DLTS spectrum with a characteristic peak is obtained as shown in the bottom of Fig. 20.38.

This peak is a signature from a specific defect level. To determine the properties of the defect (its energy level and capture cross-section), the time window ($\tau = t_2 - t_1$) is changed. In this case, different DLTS spectra are obtained at different temperatures. Using the time difference τ and the temperatures at which the peaks occur, Arrhenius plots are constructed in order to determine the defect energy level and its capture cross-section. Examples of DLTS spectra and Arrhenius plots associated with CR-DLTS are presented later (in Fig. 20.40).

A block representation of the CR-DLTS system is shown in Fig. 20.39. More details can be found in [20.79–83]. A discussion of the signal processing and averaging techniques used with this DLTS technique can be found in [20.83]. Here, the gate bias voltage of the

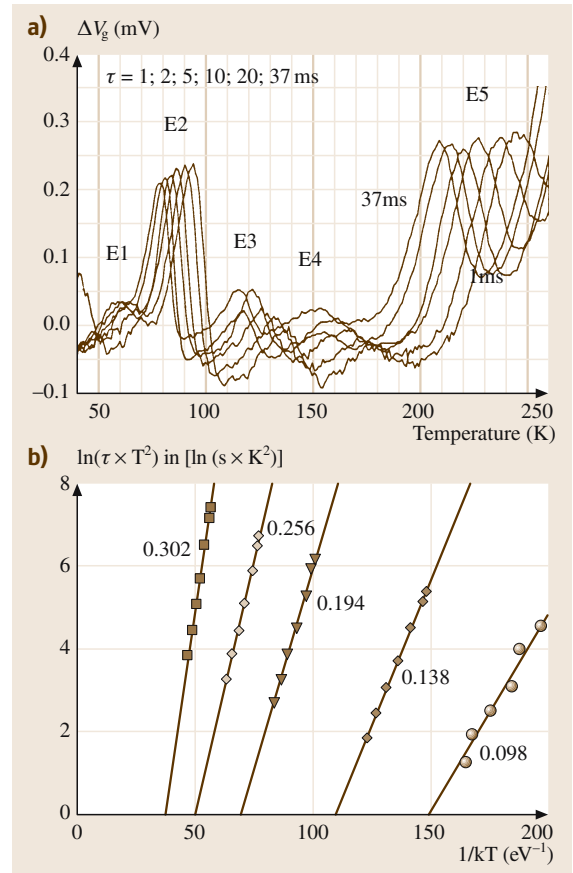

Fig. 20.40 (a) CR-DLTS spectra of a $50\ \mu\text{m} \times 20\ \mu\text{m}$ MOSFET damaged with 2.7×10^9 pronton/ cm^2 . (b) Arrhenius plot derived from the CR-DLTS spectra, showing the energies of the five traps E1–E5. After [20.80, 82]

field-effect transistor is adjusted using a feedback circuit so that the resistance corresponding to the source–drain conductance matches that of a reference resistor R_{ref} , which is typically around $1\ \text{M}\Omega$. The voltage transient due to the change in occupancy of the traps appears as a compensation voltage on the gate. This voltage change can be regarded as a threshold voltage change because the flat-band voltage of the device changes when the occupancy of the traps change. More details on how this change in the threshold is related to the traps can be found in [20.77, 79, 81].

Some important advantages of the CR DLTS technique are that the surface mobility of the MOS transistors does not need to be high, and that it is theoretically independent of the gate area of the transistor. This is expected, since the small amount of charge trapped beneath

Fig. 20.41 Effect of body bias on CR-DLTS spectra. The body bias affects the surface and bulk traps in different ways

the gate must be balanced by a correction voltage applied across a relatively small gate–substrate capacitance.

Figure 20.40a shows six DLTS spectra for a JFET damaged with 2.7×10^9 protons/cm² [20.79, 81] with six selected rate windows. Using the temperatures at which the peaks occur and the rate windows, Arrhenius plots can be constructed as shown in

Fig. 20.40b, where the energies of five electron trap levels below the conduction band are also indicated. For the five traps, the extracted capture cross sections were 4.6×10^{-15} cm² (E1), 6.3×10^{-15} cm² (E2), 1.2×10^{-16} cm² (E3), 8.5×10^{-16} cm² (E4) and 3.4×10^{-15} cm² (E5).

Figure 20.41 shows CR-DLTS spectra as the source–body bias voltage is varied. The scans with a body bias of -1 V are lower in magnitude than those without substrate bias, except for the peak associated with the hole trap at 0.13 eV above the valence band [20.81]. When the reverse substrate bias is increased, the gate control of the space charge region near the channel decreases, meaning that fewer interface traps participate in the capture and emission of charges. However, the increased reverse substrate bias results in an increased space charge region in the silicon beneath the gate, so more bulk deep levels can participate in the capture and emission processes. This explains the increased deep-level peak (below 75 K) when -1 V is applied to the body. These differences between the CR-DLTS spectra demonstrate the ability to distinguish bulk traps from surface traps when the substrate bias of the MOSFET is varied.

Single-Crystal Silicon

21. Single-Crystal Silicon: Electrical and Optical Properties

Electrical and optical properties of crystalline semiconductors are important parts of pure physics and material science research. In addition, knowledge of parameters related to these properties, primarily for silicon and III–V semiconductors, has received a high priority in microelectronics and optoelectronics since the establishment of these industries. For control protocols, emphasis has recently been placed on novel optical measurement techniques, which have proved very promising as nondestructive and even non-contact methods. Earlier they required knowledge of the free-carrier-derived optical constants, related to the electrical conductivity at infrared frequencies, but interest in the optical constants of silicon in the visible, ultraviolet (UV) and soft-X-ray ranges has been revived since the critical dimensions in devices have become smaller.

This chapter surveys the electrical (Sect. 21.2) and optical (Sect. 21.3) properties of crystalline silicon. Section 21.2 overviews the basic concepts. Though this section is bulky and its material is documented in textbooks, it seems worth including since the consideration here focuses primarily on silicon and is not spread over other semiconductors – this makes the present review self-contained. To avoid repeated citations we, in advance, refer the reader to stable courses on solid-state physics (e.g. [21.1, 2]), semiconductor physics (e.g. [21.3]), semiconductor optics (e.g. [21.4]) and electronic devices (e.g. [21.5]); seminal papers are cited throughout Sect. 21.2.

We realize how formidable our task is – publications on electrical and optical properties of silicon amount to a huge number of titles, most dating back to the 1980s and 1990s – so any review of this subject will inevitably be incomplete. Nevertheless, we hope that our work will serve as a useful shortcut into the silicon world for a wide audience of applied physics, electrical and optical engineering students.

21.1 Silicon Basics

21.1.1 Structure and Energy Bands

Normally silicon (Si) crystallizes in a diamond structure on a face-centered cubic (f.c.c.) lattice, with a lattice constant of $a_0 = 5.43 \text{ \AA}$. The basis of the diamond structure consists of two atoms with coordinates (0, 0, 0) and $a_0/4(1, 1, 1)$, as seen in Fig. 21.1. Other solids that can

crystallize in the diamond structure are C, Ge and Sn. The important notion for the electronic band structure is the Brillouin zone (BZ). The BZ is a primitive cell in the reciprocal-space lattice, which proves to be a body-centered cubic (b.c.c.) lattice for an f.c.c. real-space lattice. For this case, the BZ with important reference points and directions within it is shown in Fig. 21.2.

Fig. 21.1 Diamond crystal structure of Si

The states of electrons in solids are described by wave functions of the Bloch type

$$\psi(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} u_{s\mathbf{k}}(\mathbf{r}), \quad (21.1)$$

where \mathbf{k} is the wave vector that runs over reciprocal space, s is a band index and $u_{s\mathbf{k}}(\mathbf{r})$ is the periodic function of the direct lattice (Bloch amplitude). Both $u_{s\mathbf{k}}(\mathbf{r})$ and the corresponding energy-band spectrum $E_s(\mathbf{k})$ are periodic in \mathbf{k} , which allows one to restrict consideration

Fig. 21.2 Brillouin zone of the f.c.c. lattice

to within the BZ. The bands are arranged so that there are energy regions for which no states given by (21.1) exist. Such forbidden regions are called energy gaps or band gaps and result from the interaction of valence electron with the ion cores of crystal. In semiconductor science the term *band gap* is accepted for the energy distance between the maximum of $E_s(\mathbf{k})$ for the highest filled (valence) band and the minimum of $E_s(\mathbf{k})$ for the lowest empty (conduction) band (denoted by E_g). The band gap is called *direct* if the aforementioned maximum and minimum occur at the same point of the BZ, e.g. Γ (Fig. 21.2), and *indirect* if they occur at different points of the BZ, e.g. Γ and X (Fig. 21.2).

Si is an indirect-band-gap semiconductor with $E_g = 1.1700$ eV at 4.2 K. The calculated energy-band structure, that is the curves of $E_v(\mathbf{k})$ for selected directions in the BZ, is shown in Fig. 21.3a. The conduction-band minimum lies at six equivalent points Δ on the Γ -X lines (Fig. 21.2). In some vicinity (called the *valley*) of every such point the band spectrum is quadratic in \mathbf{k} , e.g. for the valley $\langle 100 \rangle$

$$E_c(\mathbf{k}) = E_{c0} + \frac{\hbar^2 (k_x - k_0)^2}{2m_l} + \frac{\hbar^2 (k_y^2 + k_z^2)}{2m_t}, \quad (21.2)$$

where $k_0 \approx 1.72\pi/a_0$, m_l and m_t are the longitudinal and transverse effective masses. The spectra for other five valleys are obtained from (21.2) by 90° rotations and inversions $k_0 \rightarrow -k_0$. Though the constant-energy surface for (21.2) is an ellipsoid (Fig. 21.3b), the density of states (DOS) proves to be the same as for an isotropic parabolic spectrum with an effective mass

$$m_{de} = 6^{2/3} m_l^{1/3} m_t^{2/3}, \quad (21.3)$$

which is called the *DOS effective mass*. Another mass, m_{ce} , which appears in the direct-current (DC) and optical conductivity formulas, is defined via the harmonic mean

$$\frac{1}{m_{ce}} = \frac{1}{3} \left(\frac{1}{m_l} + \frac{2}{m_t} \right). \quad (21.4)$$

For this reason, m_c is called the *conductivity/optical effective mass*. Equation (21.2) holds at $E_c - E_{c0} < 0.15$ eV, but at larger energies the ellipsoids warp strongly, especially near the X point; the change of the spectrum with energy is mostly due to the increasing m_t , while m_l increases weakly [21.6].

The valence-band maximum is at the Γ point ($\mathbf{k} = 0$), where the Bloch-wave state $u_{n0}(\mathbf{r})$ has the full symmetry of an atomic p-orbital, being six-fold degenerate in the nonrelativistic limit. The spin-orbit interaction splits

off from the bare band top a four-fold degenerate $p_{3/2}$ level up by $1/3\Delta_{so}$, and a two-fold degenerate $p_{1/2}$ level down by $-2/3\Delta_{so}$. The spectrum at $\mathbf{k} \neq 0$, even at energies near the top E_{v0} , is very complex. It consists of three branches, which are in general nonparabolic and nonisotropic [21.7]. At $E_{v0} - E_v \ll \Delta_{so}$ there are two nonparabolic anisotropic $p_{3/2}$ -derived sub-bands with the energy spectra

$$E_{v1,2}(\mathbf{k}) = E_{v0} + \frac{\hbar^2}{2m_0} \left[Ak^2 \pm \sqrt{B^2k^4 + C^2(k_x^2k_y^2 + k_x^2k_z^2 + k_y^2k_z^2)} \right],$$

$$A < 0 \quad (21.5)$$

and at $E_{v0} - E_v \ll 2\Delta_{so}$ there is an isotropic parabolic $p_{1/2}$ -derived split-off band with the energy spectrum

$$E_{v3}(\mathbf{k}) = E_{v0} - \Delta_{so} + \frac{\hbar^2k^2}{2m_0} A',$$

$$A' < 0. \quad (21.6)$$

Here m_0 is the free electron mass, A , B , C and A' are inverse hole-mass parameters (for small Δ_{so} , $A' \approx A$). In (21.5) the $+$ sign corresponds to heavy holes and the $-$ sign to light holes. The constant-energy surfaces for (21.5) are warped spheres (Fig. 21.3c), the DOS is nevertheless parabolic and is described by the effective mass

$$m_{dh} = \left(m_{d1}^{3/2} + m_{d2}^{3/2} \right)^{2/3}, \quad (21.7)$$

where $m_{d1,2}$ are the partial DOS effective masses. Quite different masses enter various physical quantities for heavy (light) holes, and are complicated functions of A , B and C ([21.9]); however, the split-off band is characterized by only one effective mass: $m_3 = m_0/|A'|$.

These band-structure parameters, obtained from cyclotron-resonance data and calculations, are presented in Tables 21.2 and 21.3. The unreferenced values of m_{de} , m_{ce} and m_3 were calculated from the referenced data using (21.3, 4) and the assumption $A' = A$. Optical data for m_{ce} are discussed in Sect. 21.3, while the specific-heat data for m_{de} are not considered here.

Considerable uncertainty and errors in the values of B and C have a small effect on the light-hole effective-mass values (m_{d2} and optical m_{c2}) but lead to an ambiguity in the heavy-hole effective-mass (m_{d1} and optical m_{c1}) values (Table 21.3). In each data set $m_{d2} \approx m_{c2}$, which means that an isotropic approximation is reasonable for the light-hole spectrum.

Fig. 21.3 Electronic band structure of Si: (a) Energy dispersion curves near the fundamental gap. After [21.8] with permission;

Fig. 21.3 (b) The constant-energy ellipsoids of the conduction band;

The experimental data [21.10, 11] and band-structure calculations [21.12] are in good agreement; the former is used in theoretical papers on hole transport in Si [21.13, 14].

Nonparabolic parts in the electron [21.6] and hole spectra [21.7] lead to apparent dependence of effective-mass measurements on the temperature and carrier concentration [21.15]. Recently the DOS mass issue was revisited [21.16] in connection with the intrinsic carrier concentration.

In highly purified Si electrons and holes are thermally generated with equal concentrations ($n = p$), equal to the intrinsic concentration n_i given by

where k_B and h are the Boltzmann and Planck constants, respectively, and T is the absolute temperature. To assess $n_i(T)$ theoretically one should take into account possible changes of $m_{de,h}$ and E_g with T . An early experimental plot of $n_i(T)$ for Si is shown in Fig. 21.4, giving $n_i(300\text{ K}) = 1.38 \times 10^{10}\text{ cm}^{-3}$. This and the early textbook value ($1.45 \times 10^{10}\text{ cm}^{-3}$) do not fit (21.8) with the established low-temperature values of $m_{de,h}$ and $E_g(300\text{ K}) = 1.1242\text{ eV}$, giving $(0.662\text{--}0.694) \times 10^{10}\text{ cm}^{-3}$ for the best available data.

In impure samples $n \neq p$; the charge-neutrality condition is then

together with the known expressions for n , p (with $np = n_i^2$ holding until the carriers become degenerate) and the concentrations of charged donors N_d^+ and acceptors N_a^- via the Fermi energy E_F and impurity ionization energies

E_d and E_a allows one to calculate E_F (and hence all the concentrations) as a function of T and doping.

An impurity is called *shallow* if $|E_{c(v)0} - E_{d(a)}| \ll E_g$, and *deep* if $|E_{c(v)0} - E_{d(a)}| \approx 0.5E_g$. Shallow group V donors (Sb, P, As) and group III acceptors (B, Al, Ga, In) are well soluble in Si [21.25]. The ionization energy was calculated using the effective-mass approximation, and the Bohr model for donors [21.26–28] (Kohn and Luttinger, 1955; Kohn, 1955) and acceptors (Luttinger and Kohn, 1955). The value of $E_{d(a)}$ calculated in this way is insensitive to the specific shallow donor (acceptor). Actual thermal (i.e. retrieved from electrical measurements) ionization energies are given in Table 21.1. It is seen that shallow impurities have different ionization energies. This difference is small for donors and larger for acceptors. The same trend was observed for optical ionization energies, although they are different from the thermal values [21.29,30]. For shallow impurities, $E_{d(a)}$ decreases as doping becomes heavier, and becomes zero as $N_{d(a)}$ approaches the corresponding insulator–metal transition concentration [21.31].

Deep impurities (except for Mn, Fe and Zn) are amphoteric, i.e. they act simultaneously as donors and acceptors. For such a donor (acceptor) state, the level

may lie closer to the valence (conduction) than the conduction (valence) band. The deep impurities are mostly unionized at room temperature due to their large $E_{d(a)}$, so their direct contribution to n or p is negligible. The unionized deep impurities may, however, trap the carriers available from the shallow impurities or injection, thus decreasing the conductivity or the minority-carrier lifetime. Atoms that behave in Si in this manner, for example Au, Ag and Cu, are added for lifetime control. The properties of these impurities in Si have been studied in detail (see, e.g., [21.32, 33]).

21.1.3 Carrier Concentration, Electrical and Optical Properties

Concentration and Electrical Measurements

Measurements of carrier concentrations, as well as electrical and optical characteristics are most tractable if either $n \gg p$ (strongly n-type conduction) or $p \gg n$ (strongly p-type conduction). Since the np product is constant versus doping, the contribution of minority carriers to the conductivity becomes unimportant when $N_{d(a)}$ increases significantly over n_i . A standard route for determining $n(p)$ is Hall-effect measurements. The Hall coefficient R^H , measured directly on a long thin slab in a standard crossed electric and magnetic field configuration, is retrieved by

$$R^H = 10^{-8} \frac{V_H d}{IB}, \quad (21.10)$$

where V_H is the Hall voltage (Volts), I is the current (Amps), d is the sample thickness (cm) in the z -direction, and B is the magnetic field strength (Gauss) applied in this direction. There are two limiting cases. One, the high-field regime is defined by $qB\tau/mc \gg 1$, where m and τ are the appropriate mass and relaxation-time parameters, respectively. In this case

$$\begin{aligned} R_e^H(\infty) &= -\frac{1}{qn}, \\ R_h^H(\infty) &= \frac{1}{qp}. \end{aligned} \quad (21.11)$$

The other, low-field, regime holds with the opposite inequality; in this regime

$$\begin{aligned} R_e^H(0) &= -\frac{r_e}{qn}, \\ R_h^H(0) &= \frac{r_h}{qp}, \end{aligned} \quad (21.12)$$

where the constant of proportionality $r_{e(h)}$, called the electron (hole) Hall factor, depends on the details of the

scattering process and band structure. Thus the majority-carrier concentration is determined directly from $R_{e(h)}^H$ using a high-field Hall measurement. For typical laboratory magnetic fields, this regime is attainable only with extremely high mobility and low effective mass, which excludes moderately and heavily doped Si, for which very high magnetic fields are required. In some cases the Hall factor is quite close to unity, e.g. $r_e = 3\pi/8$ for the phonon scattering in the isotropic and parabolic (standard) band.

The electrical properties are fully described by the drift-diffusion relation for the electron (hole) current density $j_{e(h)}$

$$\begin{aligned} j_e &= -qn v_{de} + qD_e \nabla n, \\ j_h &= qp v_{dh} - qD_h \nabla p, \end{aligned} \quad (21.13)$$

where $v_{de} = -\mu_e E$ ($v_{dh} = \mu_h E$) is the drift velocity, $\mu_{e(h)}$ is the drift mobility, E is the electric field strength, and $D_{e(h)}$ is the diffusion coefficient; in general, $\mu_{e(h)}$ and $D_{e(h)}$ depend on E . In the homogeneous case (21.13) converts into the material equation $j_{e(h)} = \sigma_{e(h)} E$, where $\sigma_{e(h)} = qn\mu_{e(h)}$ is the electron (hole) conductivity; the total conductivity equals $\sigma = \sigma_e + \sigma_h$. In the weak-field DC (Ohm) and alternating current (AC: microwave or light, except for intense laser, irradiation) regimes, $D_{e(h)}$ is proportional to $\mu_{e(h)}$ being both constant versus E , depending on the radiation frequency ω .

Combining the high-induction Hall and Ohm resistivity ($\rho = \sigma^{-1}$) measurements one obtains the drift mobility

$$\mu_{e(h)} = R_{e(h)}^H(\infty) \sigma. \quad (21.14)$$

Replacing $R_e^H(\infty)$ by $R_e^H(0)$ in the right-hand side of (21.14), one arrives at the so-called Hall mobility

$$\mu_{e(h)}^H = R_{e(h)}^H(0) \sigma = r_{e(h)} \mu_{e(h)}, \quad (21.15)$$

which never equals the drift mobility, although it may be fairly close to it in the cases mentioned above. In general, to extract $n(p)$ from $R_e^H(0)$, the calculation of the $r_{e(h)}$ factor is completed. Magnetoresistance (MR), i.e. ρ versus B measurement, is an important experimental tool as well. Another established method is the Haynes–Shockley experiment, which allows one to measure the minority-carrier drift mobility. In high-electric-field conditions, a noise-measurement technique is used. A relatively novel, time-of-flight technique was used in the latest (to our knowledge) mobility and diffusion-coefficient measurements on lightly doped crystalline Si samples, both in the low- and high-field regimes [21.14].

Basic Optical Parameters

The electromagnetic response of homogeneous nonmagnetic material is governed by the dielectric constant tensor ε , which connects the electric displacement vector \mathbf{D} inside the material to \mathbf{E} through the material equation $\mathbf{D} = \varepsilon \mathbf{E}$. For cubic crystals, such as Si, ε is a scalar. An effective-medium homogeneous dielectric constant may be attributed to inhomogeneous and composite materials if the nonhomogeneity feature size is smaller than the radiation wavelength $\lambda = 2\pi c/\omega$. Actually, ε characterizes the material's bulk and therefore loses its sense in nanoscale structures (superlattices, quantum wells etc). The dependence $\varepsilon(\omega)$ expresses the optical dispersion in the material. The dielectric constant is usually represented via its real and imaginary parts: $\varepsilon = \varepsilon_1 + i\varepsilon_2$ ($\varepsilon_2 \geq 0$), connected to each other by the Kramers–Kronig relation (KKR)

$$\varepsilon_1(\omega) = 1 + \frac{2}{\pi} \int_0^{\infty} \frac{\Omega}{\Omega^2 - \omega^2} \varepsilon_2(\Omega) d\Omega. \quad (21.16)$$

At low frequency (radio, microwave), in the absence of magnetic fields, $\varepsilon_1 \approx \varepsilon(0)$ and ε_2 , which is responsible for dielectric loss, is small. At optical wavelengths, from far-IR to soft X-rays, the basic quantity is the complex refractive index $\sqrt{\varepsilon} = n + ik$. The real refractive index n , which is responsible for wave propagation properties, and the extinction index k , responsible for the field attenuation, are referred to as *optical constants*. They are related to the dielectric constant via:

$$\begin{aligned} \varepsilon_1 &= n^2 - k^2, \\ \varepsilon_2 &= 2nk, \\ n &= \sqrt{\frac{(\varepsilon_1^2 + \varepsilon_2^2)^{1/2} + \varepsilon_1}{2}}, \\ k &= \sqrt{\frac{(\varepsilon_1^2 + \varepsilon_2^2)^{1/2} - \varepsilon_1}{2}}. \end{aligned} \quad (21.17)$$

21.1.4 Theory of Electrical and Optical Properties

Boltzmann–Equation Approach

The response of carriers in a band to perturbations away from the thermal–equilibrium state, such as applied electric and magnetic fields or impinging electromagnetic radiation, is described by the deviation of the carrier distribution function $f_s(\mathbf{k}, \mathbf{r}, t)$ from the equilibrium Fermi–Dirac distribution $f_0[E_s(\mathbf{k})]$. The current density equals $\mathbf{j}_s = q \int \mathbf{v}_s(\mathbf{k}) f_s(\mathbf{k}, \mathbf{r}, t) d\mathbf{k}$, where $\mathbf{v}_s(\mathbf{k}) = \frac{\partial E_s(\mathbf{k})}{\hbar \partial \mathbf{k}}$ is the microscopic carrier velocity and the integration is performed over the BZ. The process that balances the external perturbations is scattering of carriers by lattice vibrations (phonons), impurities and other carriers. Impurity scattering dominates transport at low temperatures and remains important at room temperature for moderate and high doping levels, although carrier–carrier scattering also becomes appreciable. Under appropriate conditions, one being that $\hbar\omega \ll \bar{E}$ (where \bar{E} is the average carrier kinetic energy), $f_s(\mathbf{k}, \mathbf{r}, t)$ satisfies the quasi-classical Boltzmann kinetic equation. In the opposite, quantum, range, radiation influences the scattering process. Generalized kinetic equations, which interpolate between the quasi-classical and quantum regimes, have also been derived [21.34].

There exist various methods of solving the quasi-classical Boltzmann equation. The relaxation-time method, variational method [21.35–37] for low electric fields, and displaced–Maxwell–distribution approximation [21.38] for high electric fields, were used in early studies. In the last three decades the Monte Carlo technique [21.39], which overcomes limitations inherent to these theories and allows one to calculate subtle details of the carrier distribution, has been applied to various semiconductors, including crystalline Si [21.14]. If $\hbar\omega \ll \bar{E}$, the kinetic and optical characteristics are calculated well using transition probabilities between carrier states, with the radiation quantum absorbed or emitted [21.40]. The most problematic is the interme-

Table 21.4 Parameters of the phonon modes in crystalline Si

Mode	Energy (K)				Sound velocity
LO	760	700–735 ^a	560	580	
TO	760	–	630–690 ^a	680	
LA	0	240–260	500–510 ^a	580	8.99×10^5 cm/s
TA	0	140–160	210–260	220	5.39×10^5 cm/s
q	Γ	Δ	S	X	

^a [21.19]

mediate range – generalized kinetic equations have been shown to recover the extreme ranges, but no working methods have been developed for solutions at $\hbar\omega \approx E$, to the best of our knowledge. The relaxation-time approximation has proved to work well in many cases of scattering in Si. In this framework, the basic quantity is the relaxation-time tensor $\tau_s(E)$, where s is the index indicating the conduction or valence band, and E is the carrier kinetic energy. For electron valleys, $\tau_c(E)$ has the same symmetry as the respective effective-mass tensor – it is diagonal with principal values of, e.g., τ_l , τ_t , τ_t for $\langle 100 \rangle$ etc. For scalar holes $\tau_{1,2}(E)$ can only be introduced in the isotropic-bands approximation. The mobility and the Hall factor for weak electric fields in the relaxation-time approximation are given by

$$\mu_e(\omega) = \frac{q}{3} \left\langle \frac{\tau_l/m_l}{1 - i\omega\tau_l} + \frac{2\tau_t/m_t}{1 - i\omega\tau_t} \right\rangle, \\ r_e = \frac{3 \langle 2\tau_l\tau_t/m_l m_t + (\tau_t/m_t)^2 \rangle}{\langle \tau_l/m_l + 2\tau_t/m_t \rangle^2}; \quad (21.18)$$

$$\mu_h(\omega) = \frac{q}{1 + \beta} \left\langle \frac{\tau_1/m_1}{1 - i\omega\tau_1} + \frac{\beta\tau_2/m_2}{1 - i\omega\tau_2} \right\rangle, \\ r_h = \frac{(1 + \beta) \langle (\tau_1/m_1)^2 + \beta(\tau_2/m_2)^2 \rangle}{\langle \tau_1/m_1 + \beta\tau_2/m_2 \rangle^2}, \quad (21.19)$$

where the angular brackets indicate averaging with the weight $-E^{3/2} f'_0(E)$, $\beta = (m_{d2}/m_{d1})^{3/2}$ is the density ratio of light holes to heavy holes, and the option for a nonparabolic band is retained.

Lattice Scattering

Deformational phonons – longitudinal, transverse acoustical (LA, TA) and optical (LO, TO) – mediate carrier–lattice scattering in Si. The phonon modes are presented in Table 21.4, where \mathbf{q} is a point in the phonon BZ. The points Δ and S correspond to the scattering process, where the electron transits between the bottoms of two perpendicularly (f) and parallel (g) oriented valleys, respectively. The phonon energies are precise at the points Γ and X, as determined by neutron-scattering techniques [21.42], but uncertain at Δ and S, since in this case only estimation and fitting methods were available.

The rigid- and deformable-ion lattice models have been used to obtain the carrier–phonon interaction for

electrons [21.43] and holes [21.44]. A deformation-potential theory of the interaction with long-wavelength phonons, which takes the crystal symmetry and band structure fully into account in a phenomenological manner, has been developed. This theory deduces two constants, Ξ_u , Ξ_d , for the conduction band [21.45] and four, a , b , d , d_{opt} , for the valence band [21.46,47], which are presented in Table 21.5. The deformation-potential theory has been used to calculate the acoustic scattering-limited mobility in n-Si [21.48] and p-Si [21.49]. Later, optical-phonon scattering, along with an approximate valence-band spectrum instead of (21.5), were taken into account [21.13, 14].

The matrix elements of electron–phonon interaction between wave functions of different valleys are not taken into account by the deformation-potential theory. For inter-valley transitions, other than the three marked in Table 21.4 by the superscript ‘a’, the matrix elements calculated at the valley-bottom wave vectors are zero [21.43, 50]. The actual scattering probabilities are never zero; for those forbidden by selection rules [21.43, 50] one should take into account the wave-vector offset at the final scattering state, which gives nominally small, but unknown values. Several inter-valley scattering models have been tried to fit the theoretical formulas to the mobility data in lightly doped n-Si: with one allowed TO and one forbidden TA phonon [21.51], one allowed TO phonon [21.52] and more involved combinations of the transitions [21.53, 54]. The scattering of electrons by long-wavelength optical phonons, regarded as a cause of drift-velocity saturation at high electric fields [21.38], is forbidden in Si [21.43]. In n-Si, by all accounts, the cause may be the allowed g-phonon (Table 21.4) scattering [21.54].

Impurity Scattering

There are two types of impurity scattering – by ionized and neutral impurities. The latter is the dominant impurity scattering for uncompensated, light or moderate shallow-impurity doping, at low T . In samples doped with deep impurities, neutral-impurity scattering may also show up. At elevated T , when shallow impurities are increasingly ionized, ionized-impurity scattering is the dominant impurity scattering and may compete with

Table 21.5 Deformation-potential parameters [21.41]

$T(\text{K})$	$\Xi_u(\text{eV})$	$\Xi_d + 1/3\Xi_u - a(\text{eV})$	$ b (\text{eV})$	$ d (\text{eV})$
80	8.6 ± 0.2	3.8 ± 0.5	2.4 ± 0.2	5.3 ± 0.4
295	9.2 ± 0.3	3.1 ± 0.5	2.2 ± 0.3	–

phonon scattering, depending on $N_{d(a)}$. Lastly, in heavily doped samples, where the impurities are ionized for all T , ionized-impurity scattering is dominant up to 300 K.

Early theories of impurity scattering were developed for carriers in parabolic bands, scattered by hydrogen-like centers. For neutral impurities the s -scattering cross section [21.55] and a cross section that takes allowance of the scattered carrier's bound state [21.56] were adopted. For ionized centers, use was made of the Coulomb scattering cross section, cut off at a small angle depending on $N_{d(a)}$ [21.57], and the screened Coulomb potential cross section, calculated in the Born approximation [21.58–60]. These theories consider scattering by the donors and acceptors on an equal footing. The use of the Conwell–Weisskopf formula for $\tau_s(\varepsilon)$ declined towards the end of the 1950s, while the corresponding Brooks–Herring (BH) formula became widespread, mostly due the consistency of its derivation, even though none of the assumptions for its validity are completely satisfied. This formula was corrected [21.61], on account of the band carrier's degeneracy, compensation and screening by carriers on impurity centers. The discrepancy between experiment and the BH formula, revealed during three decades of studies, have been thoroughly analyzed [21.62].

Modifications and developments made to overcome the drawbacks of the BH formula are worth mentioning. Taking the multi-valley band structure into account did not invalidate the relaxation-time method as such, but resulted in essentially different $\tau_1(E)$ and $\tau_1(E)$ [21.63, 64]. These formulas have also been discussed [21.65] in light of the scattering anisotropies measured in n-Si [21.66]. To overcome limitations of the Born approximation exact, although limited only to the standard band, phase-shift analysis was employed [21.67]. Including a non-Coulomb part of the impurity potential [21.68] made it possible to explain in part the difference in mobility of n-Si samples doped with different donors [21.25]. Lastly, Monte Carlo simulations of the impurity scattering, improving the agreement between theory and experiment for n-Si, have recently been reported [21.69]. The ionized-impurity scattering in p-Si was considered in the approximation of isotropic hole bands [21.70]. We are not aware of any theoretical papers on the subject, which used anisotropic energy spectra given by (21.26) in the case of p-Si.

Carrier–Carrier Scattering

Carrier–carrier scattering becomes important as n or p increases, along with increasing N_d^+ or N_a^- . The relaxation-time concept does not apply for

this mechanism. Carrier–carrier collisions redistribute the carrier's energy in a chaotic manner that was presumed to cause a decrease in the net mobility due to other mechanisms [21.71]. For the standard band, the effects of electron–electron scattering were modeled using the variational method, which predicted a $\approx 30\%$ reduction in the ionized-impurity scattering-limited mobility [21.72]; close results were obtained using another, quite different, method [21.73]. Hole–hole scattering and electron–hole scattering were also considered [21.74] in the standard band. Due to ignorance of the specific band-structure features, the results of these papers had limited relevance to Si. The effect of electron–electron scattering has been recast [21.75] for the multi-valley band structure using the generalized Drude approximation (GDA). At DC, the GDA corresponds to the zeroth-order approximation of the variational method, which highly overestimates [21.72] the effect considered.

Dielectric Constant

In Si the current carriers are well decoupled from the host electrons, so the Maxwell equations result in a unique decomposition of the dielectric constant

$$\varepsilon(\omega) = \varepsilon_L(\omega) + \varepsilon_C(\omega), \quad \varepsilon_C(\omega) = i \frac{4\pi\sigma(\omega)}{\omega}. \quad (21.20)$$

Here $\varepsilon_L(\omega)$ is the host contribution, which is indirectly influenced by the carriers. The direct effect of the carriers on the dielectric constant is the conductivity contribution $\varepsilon_C(\omega)$. As seen from (21.20), doped Si behaves at DC as a metal. The asymptote at high frequencies (IR for Si) is $\varepsilon_{C,s}(\omega) \approx -(\Omega_{pl,s}/\omega)^2$, where $s = e$ or h , and $\Omega_{pl,s}$ are the bare plasma frequencies given by

$$\begin{aligned} \Omega_{pl,e}^2 &= \frac{4\pi q^2 n}{m_{ce}}, \quad \frac{1}{m_{ce}} = \frac{1}{3} \left\langle \frac{1}{m_1} + \frac{2}{m_t} \right\rangle, \\ \Omega_{pl,h}^2 &= \frac{4\pi q^2 p}{m_{ch}}, \quad \frac{1}{m_{ch}} = \frac{1}{1+\beta} \left\langle \frac{1}{m_1} + \frac{\beta}{m_2} \right\rangle, \end{aligned} \quad (21.21)$$

resulting from (21.18, 19, 20), irrespective of the scattering model. Due to this asymptote and (21.20) $\varepsilon_1(\omega)$ should become zero at some frequency $\omega_{pl,s}$ and doped Si should behave optically as a dielectric at $\omega < \omega_{pl,s}$ and as a metal at $\omega > \omega_{pl,s}$. True plasma frequencies are estimated roughly as $\omega_{pl,s} \approx \Omega_{pl,s}/n_L$, where $n_L = \text{valrange}3.423.44$ is the Si host refractive index in the IR. For the parabolic bands, m_{ce} has already been presented in Table 21.2, and $m_{ch} = (0.33\text{--}0.39)m_0$ us-

ing the data of Table 21.2, with the assumption that $m_{1,2} = m_{c1,2}$.

General formulas for $\varepsilon_C(\omega)$ are rather involved because of the averaging over E they contain, and so are rarely used. The Drude formula

$$\varepsilon_{C,s}(\omega)|_{\text{Drude}} = \frac{i}{\omega} \cdot \frac{\Omega_{\text{pl},s}^2}{\gamma_s - i\omega}, \quad (21.22)$$

where γ_s are adjustable phenomenological damping parameters, is often employed instead [21.76]. To match the behavior of $\varepsilon_C(\omega)$ at $\omega \rightarrow 0$ one should put $\gamma_s = 1/\tau_{0,s}$ in (21.22), where

$$\begin{aligned} \tau_{0,e} &= \frac{m_{ce}}{3} \left\langle \frac{\tau_1}{m_1} + \frac{2\tau_1}{m_1} \right\rangle; \\ \tau_{0,h} &= \frac{m_{ch}}{1+\beta} \left\langle \frac{\tau_1}{m_1} + \frac{\beta\tau_2}{m_2} \right\rangle \end{aligned} \quad (21.23)$$

are the DC mobility relaxation times. Such an adjustment was shown to work poorly in n-Si [21.77]. On the other hand, putting $\gamma_s = \gamma_{\infty,s}$ in (21.22), where

$$\begin{aligned} \gamma_{\infty,e} &= \frac{m_{ce}}{3} \left\langle \frac{1}{m_1\tau_1} + \frac{2}{m_1\tau_1} \right\rangle; \\ \gamma_{\infty,h} &= \frac{m_{ch}}{1+\beta} \left\langle \frac{1}{m_1\tau_1} + \frac{\beta}{m_2\tau_2} \right\rangle, \end{aligned} \quad (21.24)$$

allows one using the Drude formula to match *two* leading at $\omega \rightarrow \infty$ terms in the power series expansion of $\varepsilon_C(\omega)$ with respect to ω^{-1} . Thus (21.22) with the above adjustments may serve as an overall interpolation if the *high-frequency* relaxation time, $\tau_{\infty,s} = 1/\gamma_{\infty,s}$ turns out to be close to $\tau_{0,s}$. A Drude formula, empirically adjusted in IR has been devised for n-Si [21.78].

Using $\tau_{\infty,s}$ instead of $\tau_{0,s}$ in the mobility is a prerequisite for GDA at DC. As discussed above, the Boltzmann-equation-based formulas are valid in the range $\lambda \gg \lambda_q = hc/\bar{E}$. For nondegenerate carriers $\lambda_q(\text{cm}) \approx 1.4388/T$, while in Si for n or p up to $\approx 10^{20} \text{ cm}^{-3}$ the carrier degeneracy (if present) stops much below 300 K, so the validity of the $\varepsilon_C(\omega)$ formulas considered is restricted to the far-IR and longer wavelengths. To properly describe $\varepsilon_C(\omega)$ in the near- and mid-IR range, ω -dependent GDA has been suggested [21.79]. In this approximation one replaces γ_s in (21.22) by an ω -dependent damping $\gamma_s(\omega)$, which is then determined by comparison of the first imaginary term in the expansion of the thus-generalized Drude formula, i.e. $(\Omega_{\text{pl},s}/\omega)^2 \gamma_s(\omega)/\omega$, with $\varepsilon_2(\omega)$ calculated using the methods of transition probabilities or perturbations for correlation functions.

In Si, unlike semiconductors with ionic bonds (e.g. $\text{A}^{\text{III}}\text{B}^{\text{V}}$), the elementary cell has no dipole moment and hence no quasi-classical optical-phonon contribution in $\varepsilon_L(\omega)$ is present. However, several weak IR absorption bands, attributed to two-phonon interaction of light with the Si lattice, are observed. Of these bands the most prominent is that peaked at $16.39 \mu\text{m}$, which undergoes about a twofold increase in absorption upon increasing the temperature from 77 to 290 K. Comparable to that, the $9.03 - \mu\text{m}$ absorption band, observed in pulled Si crystals, was attributed to Si–O bond stretching vibrations [21.80]. At $\lambda < 1.2 \mu\text{m}$, where $\varepsilon_L(\omega)$ dominates the dielectric constant irrespective of the doping, $\varepsilon_{2L}(\omega)$ is accounted for by inter-band electronic transitions. The spectral bands of $\varepsilon_{2L}(\omega)$ correspond to the absorption of photons with energies close to the band gaps. Bare indirect-band-gap transitions, that necessitates lowest energy, is forbidden, but perturbation correction in the electron–phonon interaction to $\varepsilon_{2L}(\omega)$ suffices to describe the observed indirect absorption band. Due to the phonons the lowest fundamental absorption, although smaller than in direct bands, increases with increasing T . In principle, $\varepsilon_{2L}(\omega)$ may be calculated by the band-structure simulation route (e.g. Kleinman and Phillips [21.6, 8, 21]), especially with the present state-of-the-art theory – $\varepsilon_{1L}(\omega)$ is then calculated using the KKR (21.16). However, applications need fast modeling, and such formulas have been developed for Si [21.81–83]. There are a few distinct doping effects on $\varepsilon_L(\omega)$:

1. Effects on the lowest band edges, both direct and indirect: the Burstein–Moss shift with increasing $n(p)$ in heavily doped samples at the degeneracy due to filling of the conduction (valence) band below (above) E_F ; band-gap shrinkage due to carrier–carrier and carrier–impurity interactions [21.84, 85] that work against the Burstein–Moss shift; and the formation of band tails because of the random potential of impurities (e.g. [21.31]).
2. Effects on higher edges, such as: E_1 (3.4 eV) – due to transitions between the highest valence band and the lowest conduction band along the Λ line in a region from $\pi/4a_0(1, 1, 1)$ to the L point on the BZ edge; and E_2 (4.25 eV) – due to transitions between the valence band at the X point and the conduction band at $2\pi/a_0(0.9, 0.1, 0.1)$ [21.8]. In this case [21.86], the electron–electron interaction plays a small role because carriers are located in a small region of the BZ, different from that where the transitions take place,

and the effect of the electron–impurity interaction is calculated using standard perturbation theory.

3. Absorption due to direct inter-conduction-band (inter-valence-band) transitions specific to the type of doping. In n-Si this is a transition from the lowest conduction band to the band that lies higher at the Δ point but crosses the former at the X point, and which gives rise to a broad absorption band peaked around 0.54 eV [21.87] and tailing of the indirect gap at heavy doping [21.88]; the theory of this contribution to $\varepsilon_{2L}(\omega)$ has been developed [21.85]. In p-Si these transitions are those between the three highest valence bands [21.7]. Absorption due to the $1 \rightarrow 2$ tran-

sition has no energy threshold, and so resembles the usual free-carrier absorption; that due to the $1 \rightarrow 3$ and $2 \rightarrow 3$ transitions appears at $\hbar\omega = \Delta_{so}$. A high-energy threshold, above which the inter-valence-band absorption becomes negligible, exists due to the near congruency of all three valence sub-bands [21.7] at large well k (this is not accounted for by (21.5, 6), which are valid at small k). In contrast, with p-Ge, the manifestation of the inter-valence-band transitions in the reflection, was proposed for p-Si [21.89], but fully reconciled later [21.85, 90]. Kane's theory of the inter-valence-band absorption [21.7] has also been revisited [21.90].

21.2 Electrical Properties

An extensive investigation of basic electrical properties was started 55 years ago, when polycrystalline Si containing B and P, was reported [21.91]. This seminal work was necessarily limited because neither single crystals nor the means for measuring below 77 K were then available. The first papers on single crystals were published five years afterwards. Since then, as techniques for fabricating quality single-crystalline silicon, such as the pulling, e.g. Czochralski (CZ), Teal–Little (TL), and floating-zone (FZ) techniques, became highly developed, many experiments on electrical properties have been published. A number of papers are considered below in historical retrospect. In the accompanying graphs additional, less cited, papers are referenced.

Though the physical mechanisms behind the electrical properties of crystalline Si have been studied and partially understood for a long time, the resulting formulas and procedures are too complicated and time-consuming to be used in electronics device modeling. In this connection, several useful, simplified but accurate, procedures for modeling mobility versus temperature, doping, injection level and electric field strength have been developed. For this issue we refer to points 2–4 in Sect. 21.2.3.

21.2.1 Ohm's Law Regime

Drift Measurements

1. The minority-carrier mobility as a function of N_d , N_a , T and ρ in n- and p-type samples is in the range 0.3–30 Ωcm [21.92]. This cited paper revealed for the first time the inapplicability, at least for holes, of

the simple $T^{-1.5}$ lattice mobility law, and presented curves of ρ versus exhaustion concentration $N = |N_d - N_a|$ in the range $10^{14} \text{ cm}^{-3} \leq N \leq 10^{17} \text{ cm}^{-3}$.

2. Measurements of μ_e in p-type and μ_h in n-type Si on 11 single crystals ranging in ρ from 19 to 180 Ωcm [21.93]. In the purest crystals, in the range 160–400 K, μ_e and μ_h obeyed the dependencies $T^{-2.5 \pm 0.1}$ and $T^{-2.7 \pm 0.1}$, respectively. The conductivity of some of these crystals, measured from 78 to 400 K, provided independent evidence for the temperature dependencies of the mobility quoted above.
3. Room-temperature drift and conductivity plus Hall-effect measurements [21.94] of μ_e and μ_h versus resistivity on an unprecedentedly large number of samples cut from CZ crystals. The largest ρ was above 200 Ωcm . The values of μ_e and μ_h obtained from both experiments in the purest crystals were reported and compared with those obtained by other authors.

Resistivity

and Galvanomagnetic Measurements

1. Room-temperature $\mu_{e(h)}^H$ as a function of $\rho_{e(h)}$ [21.95]. The crystals used were grown from Dupont hyper-pure material, with ρ of 0.01–94 Ωcm for n-type and 0.025–110 Ωcm for p-type samples. Curves of $\mu_{e(h)}^H$ versus $\rho_{e(h)}$ were calculated using the BH and combined-mobility [21.71] formulas for $m_{e(h)} = m_0$ and compared with experimental curves.
2. The first extensive experimental study of electrical conductivity and the Hall effect in TL silicon [21.96]. The properties were measured at

- temperatures of 10–1100 K on six arsenic-doped n-type samples, and one undoped, plus five boron-doped, p-type samples, covering the range from light ($N = 1.75 \times 10^{14}$ and $3.1 \times 10^{14} \text{ cm}^{-3}$) to heavy ($N = 2.7 \times 10^{19}$ and $1.5 \times 10^{19} \text{ cm}^{-3}$) doping. Compensation by unknown acceptors (donors) occurred in four lightly and moderately doped n(p)-type samples. A deviation of the lattice mobility from the $T^{-1.5}$ dependence was reported for both electrons and holes. Curves of $\mu_{e(h)}^H$ against $\rho_{e(h)}$ at 300 K were computed in the same way as by Debye and Kohane, but incomplete ionization of impurity centers was additionally taken into account.
3. First systematic study of μ_e and μ_h versus N_d and N_a , respectively, at $T = 300 \text{ K}$ [21.97]. Measurements were taken with several group V and group III impurities up to 6×10^{19} and $6 \times 10^{18} \text{ cm}^{-3}$ for n- and p-Si, respectively. Impurity concentrations were obtained by radioactive tracers or from thermal neutron activation analysis; μ_e and μ_h were calculated from these data by considering the N_d^+ and N_a^- percentages. The combination with measured $\mu_{e(h)}^H$ resulted in $r_{e(h)}$ values in agreement with theory. A comparison with a BH-formula-based theory yielded semiquantitative agreement for μ_e^H , while measured values of μ_h^H proved to be much smaller than the theoretical values.
 4. Galvanomagnetic effects in p-Si: ρ and R^H versus T and B [21.98] and MR [21.99]. Boron-doped samples cut from CZ crystals were used. In the first paper four samples, two with $\rho(300 \text{ K}) = 35 \Omega\text{cm}$ and two with $\rho(300 \text{ K}) = 85 \Omega\text{cm}$, were measured in the range 77–320 K. The dependence $\mu_h \propto T^{-2.7 \pm 0.1}$ at $B = 0$, as observed by Ludwig and Watters, was typical of the results obtained on all the samples; r_h was observed to exhibit a weak linear decrease with T in the range 200–320 K, and to be almost entirely independent of B up to $B = 1.3 \text{ T}$ in the temperature interval studied. The dependence of MR on the relative directions of current, fields and crystallographic axes was studied at 77 K and 300 K as a function of B . Large values of longitudinal MR, as large as the transverse effects in some cases, were observed, contradicting the only calculations available at that time [21.9]. To obtain data sufficient for constructing a more satisfactory model, the above study was continued in the second paper on 10 more samples, with ρ of 0.15–115 Ωcm . Measurements of three MR coefficients were carried out at a number of temperatures in the range 77–350 K. The results showed a marked dependence of the band structure and scattering anisotropies on the temperature, yet no definite model of these effects was arrived at.
 5. A comparative study of mobility in pulled and FZ crystals [21.100]. The question of the dependence of the intrinsic mobility on temperature was recast. The authors found that in FZ, contrary to pulled crystals, μ_e^H followed the $T^{-1.5}$ law in the range 20–100 K, although μ_h^H still displayed a different, viz. T^{-2} , variation with temperature. It was argued that such a disagreement with the work of Morin and Maita was due to the large content, up to 10^{18} cm^{-3} , of oxygen impurities in the pulled crystals they used, which resulted in scattering that obscured the phonon scattering.
 6. Solid analysis of electrical properties of n-Si with respect to: the ionized-impurity scattering in isotropic approximation [21.101], scattering anisotropies [21.66] and lattice scattering [21.51]. The measurements were made from 30 to 100–350 K using a set of P-doped, B-compensated, n-type samples of rather wide impurity content, yet in the range from light to moderate doping ($N_d = 4.5 \times 10^{15} \text{ cm}^{-3}$ at most). The purest samples were cut from FZ crystals while others were from CZ crystals. These authors developed a sophisticated, but robust, method of determining N_d and N_a by analysis of the R^H versus T data. With this method, in the first paper they obtained curves of μ_e versus T in the range 30–100 K, which were used to test the BH formula. In comparing the formula with the data, correction to the observed μ_e because of the phonon-scattering contribution was necessary. The BH formula was shown to provide a good quantitative description of the data when $m_e = 0.3m_0$ was used, provided that ion scattering was not too strong. When ion scattering was dominant, viz. in moderately doped samples at low T , they observed a discrepancy between the theory and data, which was attributed to electron–electron interaction. For the purpose of detecting scattering anisotropy, the MR coefficients were measured in the second paper on several relatively pure ($N_d = 8.0 \times 10^{14} \text{ cm}^{-3}$ at most) samples. The results indicated that $\tau_l/\tau_t \approx 0.67$ and $\tau_l/\tau_t > 1$ for acoustic-phonon and ionized-impurity scattering, respectively. The inter-valley phonon scattering, important at higher T , proved to be isotropic. In the third paper lattice scattering was treated. A model assuming inter-valley scattering by two-phonon modes, in addition to the intra-valley acoustic-phonon scattering, was applied to the re-

Fig. 21.5 (a) Room-temperature resistivity of Si versus N (defined in the text) for overlapping ranges of doping: (a) light to moderate;

sults of the electrical and MR measurements in the purest samples. By using the coupling constants with the phonon modes as fitting parameters, fairly good agreement was achieved between the model and experimental data on curves of μ_e versus T in the range 30–350 K, though one of the inter-valley phonon energies corresponded to a forbidden transition (Table 21.4).

7. Experimental verification of the anisotropic ion-scattering theory [21.102]. Measurements of saturated longitudinal MR and μ_e were made in fields up to 9 T at 78 K on a series of [111]-oriented phosphorus-doped samples with N_d in the range 2×10^{13} – 6×10^{16} cm^{-3} . A quantitative analysis was made that involved combined re-

Fig. 21.5 (b) moderate;

Fig. 21.5 (c) moderate to heavy;

laxation times from impurity, intra-valley, and inter-valley lattice scattering. The data agreed very well with the theory [21.103]. In samples with $N_d > 10^{16}$ cm^{-3} the neutral-impurity scattering effect was observed.

8. Refined analysis of the Hall effect and mobility in n-Si [21.53]. μ_e and n , as determined from the high-field Hall effect, were numerically analyzed for a series of n-type samples doped with Sb, P, and As. The calculations were based on the general treatment for an anisotropic parabolic band [21.48]. Lattice-scattering parameters for the inter-valley and acoustic modes were determined from a comparison of the results between theory and experiment, using as many as four inter-valley phonons. The conclusions supported the two-phonon Long model. Ionized-impurity scatter-

Fig. 21.5 (d) heavy. After [21.24] with permission

ing was calculated from the BH formula and a newer theory [21.103] and compared with experiment in favor of the latter. Neutral-impurity scattering proved

to be temperature-dependent, unlike the available model [21.55].

9. The Hall factor in n-Si versus $N_I = N_d^+ + N_a^-$ [21.106]. The experimental value of r_e was obtained from the ratio of $R_e^H(0)$ to $R_e^H(\infty)$, determined by independent methods at 77 and 350 K over a wide range of N_I . Samples were cut from non-oxygenated ingots grown in vacuum, in which $R_e^H(0)$ was measured by the standard method (Sect. 21.2). Discs were then cut from the same samples, in proximity to Hall probes, and their total resistances (given by $BR_e^H(\infty)/d$ at $\mu_e B/c \gg 1$ (Sect. 21.2), where d is the disc width) were measured in fields up to $B = 3.5$ T. To check these results, standard measurements of R_e^H in pulsed fields (Sect. 21.2) up to $B = 15$ T were made. The values of r_e were calculated from theory [21.103]. Good agreement of experiment with theoretical calculations was obtained.

Minority Carriers – Miscellaneous

Minority carriers play a crucial role in silicon-based electronic devices such as bipolar junction transistors (BJT) and solar cells, so their charge-transport parameters – concentration, recombination time, mobility and diffusion coefficient – are important for device modeling. We do not present a literature overview nor graphical and tabular material here, as we do for the case of the majority carriers, and refer the reader directly to the review papers outlined in points 5 and 6 of Sect. 21.2.3.

Irvin Curves

The curves of $\rho(300\text{ K})$ versus N , over the entire range up to the solubility limit, compiled using published data [21.104, 107] are shown in Fig. 21.5a–d, with the high-doping range shown Fig. 21.6a–d. The resistivity decreases with increasing N since the conductivity is proportional to $n(p)$ while $n(p) = N$ at $T = 300\text{ K}$. However, at large N the decrease is slower than $\propto N^{-1}$ due to the notable dependence of $\mu_{e(h)}$ on doping (see below).

Mobility and Hall Effect Versus Resistivity and Doping

Many studies have reported μ versus ρ graphically. Figure 21.7a–d summarize this information obtained before 1965. For the Hall measurements the drift mobility was recalculated from the Hall value using the Hall factor for the standard band (Sect. 21.1.3). The dependencies of $\mu_{e(h)}$ on N , $N_{d(a)}$ and on N_I at low T are more physical and allow comparison with available theories. Exam-

Fig. 21.7 (b) Hole mobility. After [21.24] with permission;

ples of such dependencies obtained by different authors are presented in Fig. 21.8a–e. Several phenomenological expressions for $\mu_{e(h)}(N, 300\text{ K})$ have been given in the literature (Sect. 21.2.3) in agreement with experimental data on charge transport in Si. We consider here two of them, for obvious reasons of space. The first [21.108]

reads

$$\mu(N_i) = \mu_{\min} + \frac{\mu_{\max} - \mu_{\min}}{1 + (N_i/N_{\text{ref}})^\alpha}, \quad (21.25)$$

where $i = a, d$, and the other fitting parameters are given in Table 21.6, the electron column of which corre-

sponds to a later best fit for Si:P [21.109], while the hole column is due to *Caughey and Thomas* [21.108]. The particular case of (21.25) with $\mu_{\min} = 0$, $\alpha = 0.5$, $N_{\text{ref}} = 10^{17} \text{ cm}^{-3}$ [21.110] has also proved useful. The second expression for Ohm's mobility versus impurity concentration,

$$\mu(N_i) = \frac{\mu_0}{\sqrt{1 + \frac{(N_i/N_{\text{eff}})S}{N_i/N_{\text{eff}} + S}}}, \quad (21.26)$$

where N_{eff} and S are fitting parameters, follows from the weak electric field limit of the more general phenomenological expression (21.31) for v_d versus E and N_i . The best-fit parameters for (21.26) can be found in Table 21.7. Fits to (21.25) and (21.26) are used in Fig. 21.8a–c. Physically, μ_{\max} in (21.25) and μ_0 in (21.26) are $\mu_{e,hL}(300 \text{ K})$, the intrinsic mobility (see below) at room temperature. Experimental data on this parameter due to different authors are presented in Table 21.8. Figure 21.8d shows a com-

parison between the mobility of holes, as minority and majority carriers, plotted against the concentration of majority impurities. At the same concentration the minority-hole mobility is strikingly larger than the majority-hole mobility. This effect may be due to the difference between scattering by attractive and repulsive centers as well as to hole–hole interaction. The variation of $\mu(N, 300 \text{ K})$ with shallow donor and accep-

Fig. 21.8 (c) Summary of data on and fits to room-temperature hole mobility versus acceptor concentration in p-Si, *open circle* – compiled experimental data [21.104], *solid circle* – lattice mobility, *full line* – fitting of Irvin's data by (21.25) due to Caughey and Thomas, and *dash-dotted line* – the best fit due to Scharfetter and Gummel ((21.26), Table 21.9) [21.14], with permission; **(d)** Mobility of holes as being minority carrier (*symbols and dashed line*), measured on devices by different authors indicated in captions, and majority carrier (*full line*) due to Thurber et al. tor species, noted in Sect. 21.1.4, is shown in Table 21.9. As can be seen, the effect – the larger $E_{d(a)}$ the lower $\mu_{e(h)}$ – is not drastic but quite noticeable. At low temperatures the impurity-scattering-limited mobility depends on the density of ionized centers, as predicted by the BH formula (or its modifications), e.g. for electrons

$$\mu_{eI} = \frac{\eta T^{3/2}}{N_I (\ln b - 1)}, \quad (21.27)$$

$$\eta = \frac{2^{7/2} k_B^{3/2} \varepsilon'^2}{\pi^{3/2} q^3 m^{*1/2}},$$

where m^* is an adjusted effective mass, $\varepsilon' = \varepsilon(0)$ is the static dielectric constant and

$$b = \frac{24\pi m \varepsilon' (k_B T)^2}{n' q^2 h^2}, \quad (21.28)$$

$$n' = n + (n + N_a) \left(1 - \frac{n + N_a}{N_d}\right).$$

For compensated n-Si $n \ll N_a$ at sufficiently low T , so $N_I = 2N_a$ and $n' = N_a(N/N_d) = N_I(1 - K)/2$, where K is the compensation ratio. Thus, disregarding the weak logarithmic dependence, μ_{eI}^{-1} proves to be linear with N_I . Such dependence is seen in the experimental data shown in Fig. 21.8e.

The Hall coefficient for lightly compensated n-Si as a function of B is shown in Fig. 21.9a. The curve for

viz. $r_e \approx 1$ on both the moderate and heavy doping sides and a maximum in between at which $r_e > 1$, is deduced from (21.23) using knowledge of the anisotropy of the mass and relaxation-time tensors. Compared to these, results for the Hall effect for holes are not available, to our knowledge.

Hall Effect and Mobility Versus Temperature
The dependencies of $r_e(T)$ and $r_h(T)$ for samples 131, 130 and 159, 127 from Table 21.10 are shown in Fig. 21.9d. The temperature dependence of R_h^H relative to its value at $T = 300$ K for another p-type sample is shown in Fig. 21.9e. Since, in the considered temperature range, p is constant with T , the dependence is fully congruent to $r_h(T)$ – in this regard the lower curve in Fig. 21.9d and the curve in Fig. 21.9e are in agreement. There is good quantitative agreement between experiment and theory for $r_e(T)$ using an exact effective-mass tensor, as shown in Fig. 21.9f. On the contrary, the Hall effect and MR in p-Si are poorly understood [21.98,99] as the energy spectra of holes is much more complicated than (21.5, 6), even for energies well above 200 K [21.7].

The $\mu_{e,h}(T)$ curves have been the subject of extensive, but to our opinion not exhaustive, studies. As discussed in Sect. 21.2, these dependencies reflect the scattering mechanisms. The basic question is that of temperature dependence due to lattice scattering, which can be measured on technologically pure, very lightly doped and negligibly compensated samples. Since such samples were not available in early studies, researchers tried to apportion the intrinsic $\mu_{e,h}(T)$ from the drift measurements, as shown in Fig. 21.10a, or from conductivity and Hall measurements combined with calculations, as shown in Fig. 21.10b. In practice the intrinsic $\mu_{e,h}(T)$ is described by the phenomenological best-fit equation

$$\mu_{e,hL}(T) = AT^{-\gamma} \quad , \quad (21.29)$$

where A and γ may vary with the carrier and measurement type, fitting interval and sample quality. Different drift measurements, in the ranges 150–300 K [21.92], and 160–400 K [21.93], resulted in very different values of A and γ for both electrons and holes. The first measurements of the Hall effect and conductivity against temperature [21.96] gave the same γ for holes as that obtained by Prince, but a drastically larger γ for electrons, as the n-type samples with the lowest N_d used were inappropriate for that purpose – one sample (131, Table 21.10), though lightly doped, was compensated ($K \approx 0.57$) and the other (130, Table 21.10) was doped in excess of 10^{15} cm^{-3} . Therefore, Morin and Maita numerically extracted the ionized-impurity scattering mobility portion (21.27, 28) and then determined γ . This procedure seems unreliable in view of the inapplicability of the BH formula with strong compensation, neglect of scattering by neutral impurities and of the spectrum and scattering anisotropies. Analogously, using (21.29) for a high-resistivity p-type Si sample [21.99], fitting to $\mu_h(T)$ resulted in the same γ as that obtained by Ludwig and Waters while fitting to $\mu_h^H(T)$ (Fig. 21.10e) resulted in an even larger γ . Using high-purity samples, for which the $\mu_e(T)$ and $\mu_h(T)$ values are presented in Fig. 21.10c, made it possible to determine a γ for $\mu_e(T)$ in agreement with that obtained by Prince, but failed to fit $\mu_h(T)$

Table 21.14 Parameters of the best fit of the intrinsic mobility to (21.29)

to (21.29) [21.100]. Long did not fit using (21.29) and calculated $\mu_{eL}(T)$ using a realistic electron spectrum and a specific inter-valley electron–phonon scattering model (Sect. 21.1.4TSnotePlease check this link.), and compared the calculation to experiment [21.51], with excellent agreement, as can be seen in Fig. 21.10d. The validity of the model [21.51] was confirmed by an independent study [21.53]. The calculation of $\mu_{eL}(T)$ was revisited on the basis of the Monte Carlo method and extended inter-valley scattering models [21.113]; the results are displayed in Fig. 21.11a along with the experimental data and fit line. We are unaware of analysis for $\mu_{hL}(T)$ comparable to that done for $\mu_{eL}(T)$, taking both the realistic hole spectrum [21.7] and full hole–phonon scattering into consideration. Another analysis [21.70] greatly simplified the problem by using relaxation-time equalization ($\tau_1(E) = \tau_2(E)$), resulting from the isotropic approximation adopted for the hole spectra (21.5), but proved insufficient to account for both Ohm’s mobility and hot-holes phenomena [21.13]. The results

of calculations based on the relaxation-time method, using only one isotropic but nonparabolic heavy-hole band [21.13], are displayed in Fig. 21.11b along with the experimental data and fit line. The best-fit parameters of (21.29) obtained by different authors are given in Table 21.14.

The effect of doping on mobility is shown in Fig. 21.12. In doped samples $\mu_{e,h}(T)$ increases with decreasing T up a maximum at some T_{\max} (the lower the sample’s purity the larger T_{\max}) and then starts to decrease. This behavior is due to competition between lattice scattering, which weakens with decreasing T , and impurity scattering, which strengthens with decreasing T , (21.27, 28, 29). In heavily doped samples scattering by impurities, while dominating the mobility, ceases to depend notably on T [(21.27, 28, 29) do not hold in this case], which results in an overall weak dependence of the observed $\mu_{e,h}(T)$ on T . These types of behavior are clearly seen in Fig. 21.12a–b. The evolution of T_{\max} with the impurity content for lightly doped, differ-

Fig. 21.12 (b) Hall mobility of p-type CZ crystals with different ρ_{300} . After [21.99] with permission;

ently compensated, n-Si is readily traced in Fig. 21.12c. The compensation is crucial for the rate of downturn of the mobility, as follows from (21.27, 28) and is confirmed by the curves for samples C and D (Table 21.11)

Fig. 21.12 (d) Summary of data on μ versus T ; symbols and lines indicate experimental data and simulations, respectively. After [21.14] with permission. Electrons: solid circle – high purity Si ($N \leq 10^{12} \text{ cm}^{-3}$, time-of-flight) [21.114], solid triangle – lightly doped compensated (Si: P 6, Table 21.13, photo-Hall effect) [21.53], open square – moderately doped with $K \approx 0.01$ (139, Table 21.10, Hall effect) [21.96], full line indicates the theoretical results for the lattice mobility [21.114], dot-dashed line gives the best fit of that mobility by an inverse power of T around room temperature ((21.29), Table 21.9); Holes: solid circle – high purity Si ($N \leq 10^{12} \text{ cm}^{-3}$, time-of-flight) [21.13], open triangle – lightly doped with $K \approx 0.01$ (F , Table 21.11, Hall effect) [21.100], open square – moderately doped with $K \approx 0.1$ (119, Table 21.10, Hall effect) [21.96], full line indicates the theoretical results for the lattice mobility, dot-dashed line gives the best fit of that mobility by an inverse power of T around room temperature ((21.29), Table 21.9) [21.13]

in Fig. 21.12c. Figure 21.12d summarizes the information on $\mu_{e,h}(T)$ for doped Si. For estimations of the

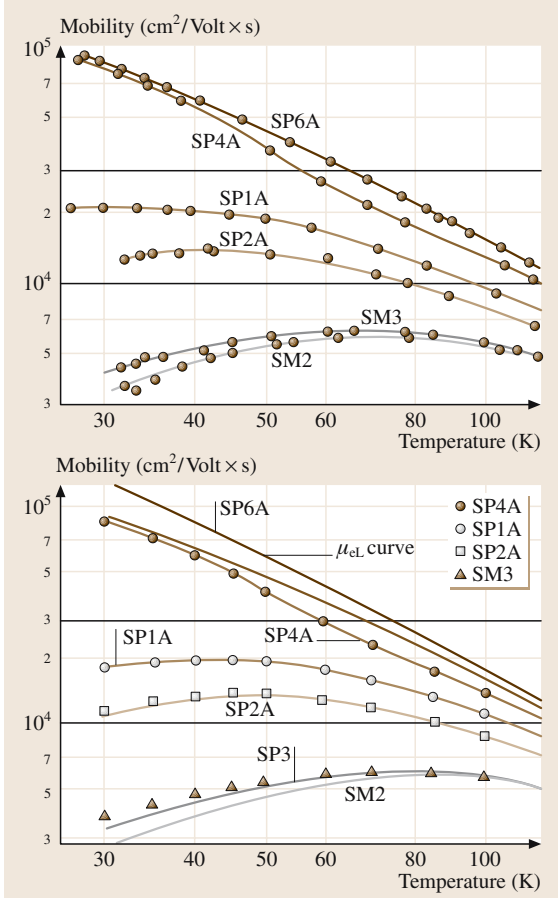

Fig. 21.13 Comparison of the theoretical results on $\mu_e(T)$ and $\mu_e^H(T)$ (symbols) with the experimental data (full lines). The indicated samples are those from Table 21.12. After [21.101] with permission

combined-scattering mobility e.g. for electrons, the Mat-tisen rule $\mu_e^{-1}(T) = \mu_{eL}^{-1} + \mu_{eI}^{-1}$, where μ_{eL} and μ_{eI} are given by (21.29) and (21.27, 28), respectively, is used (e.g. [21.100, 101]). The formula, consistently derived for nondegenerate carriers in the standard band, is

$$\mu_e(T) = \mu_{eL} + \mu_{eL}x^2 \times \left\{ \text{Ci}(x) \cos x + \left[\text{Si}(x) - \frac{\pi}{2} \right] \sin x \right\},$$

$$x = \sqrt{\frac{6\mu_{eL}}{\mu_{eI}}}, \quad (21.30)$$

where $\text{Ci}(x)$ and $\text{Si}(x)$ are integral cosine and sine, respectively, and μ_{eL} is due to acoustic-phonon scattering (with $\gamma = 1.5$) [21.71], which proved more appropri-

Fig. 21.14 Variation of reduced mobility with electric field applied to a 70 Ωcm n-Si sample along the direction (111). The electron concentration is assumed to be constant. After [21.24] with permission

ate for quantitative analysis. The comparison of (21.30) and the expression for $\mu_e^H(T)$, derived under the same conditions, with the corresponding experimental curves, using $\eta = 8.6 \times 10^{17} \text{ K}^{-1.5} \text{ cm}^2 \text{ V}^{-2} \text{ s}^{-1}$ (21.27) for an effective isotropic band mass of $m^* = 0.3m_0$, is shown in Fig. 21.13. Good quantitative agreement between the theory and experiment is observed except for the samples SM3 and SM2, in which the ionized-impurity scattering is strongest (to avoid confusion the data points for SM2 are not shown but they are as discrepant with respect to the observed mobility curve as those shown for SM3). The generalization of (21.30) to the case with spectrum and scattering anisotropies [21.103] was employed to calculate $r_e(T)$ [21.65] and to extract N_a from the mobility data [21.53]. Dakhoskii numerically explained why the above isotropic approximation [21.101] worked well, but presented no graphs of mobility versus T . Norton et al. presented graphically calculated $\mu_e(T)$ only for Si:P6, the purest of their samples. No analysis for $\mu_h(N, T)$ comparable to that done for $\mu_e(N, T)$, i.e. taking both the realistic hole spectrum and hole-phonon and hole-impurity scatterings into account, exists to our knowledge in the literature. Success of modeling based on empirically adjusted phenomenological expressions (point 2–4 in Sect. 21.2.3), though valuable for the device community, cannot be considered as such from the viewpoint of solid-state and semiconductors theories.

21.2.2 High-Electric-Field Effects

The group of effects associated with the carrier transport in high electric fields is traditionally called

Fig. 21.15 Carriers' drift velocity for E , applied along two indicated directions, measured at different indicated T by the time-of-flight method: **(a)** Electrons. After [21.116] with permission;

hot-carrier phenomena. This name was borrowed from the displaced-Maxwell-distribution method, where an effective parameter is the carrier temperature, which becomes much higher than that of the lattice, as if the field heats the carriers [21.38]. Not too much work has been published on hot-carrier phenomena in Si, but most of the existing work was overviewed in the two references cited below, and in point 3 in Sect. 21.2.3.

1. The electron drift velocity ([21.113]). Experimental results for electrons in Si obtained using a time-of-flight technique were presented for $8\text{ K} \leq T \leq 300\text{ K}$ and E in the magnitude range $1.5 \times 10^4 - 5 \times 10^4\text{ V/cm}$, oriented along the $\langle 111 \rangle$, $\langle 110 \rangle$ and $\langle 100 \rangle$ crystallographic directions. At 8 K the dependence of the transit time upon sample thickness allowed a measurement of the valley repopulation time when the electric field is $\langle 100 \rangle$ oriented. These experimental results were interpreted with Monte Carlo calculations in the same ranges of T and E . The model

Fig. 21.15 (b) Holes. After [21.13] with permission

included the many-valley structure of the conduction band of Si, acoustic intra-valley scattering with the correct momentum and energy relaxation and correct equilibrium phonon population, several inter-valley scatterings, and ionized-impurity scattering.

2. Hole drift velocity [21.13]. Drift velocities for holes in high-purity Si, were measured by a time-of-flight technique with E in the amplitude range from $3 \times 10^4 - 5 \times 10^4\text{ V/cm}$ along the $\langle 100 \rangle$, $\langle 110 \rangle$, and $\langle 111 \rangle$ directions, and at $8\text{ K} \leq T \leq 300\text{ K}$. The Ohm's mobility is theoretically interpreted on the basis of a two-band model consisting of a spherical parabolic and a spherical nonparabolic band, and relaxation-time approximation. The low- T Ohm's mobility proved to be strongly influenced by the nonparabolic structure of the heavy-hole band. The high-field region, $E = |E| \geq 103\text{ V/cm}$, was analyzed using a single, warped heavy-hole band model and a Monte Carlo technique. Anisotropy of the hot-hole drift velocity due to warping of the valence band was measured. Optical- and acoustic-phonon scattering were found to have comparable rates.

Impact ionization phenomenon are different in appearance and are not considered here in detail; see point 7 in Sect. 21.2.3.

Drift Velocity – Electric-Field Relationship

As the field strength E overcomes some limit (which depends on the lattice temperature, doping and type of carrier) the drift velocity (Sect. 21.2.3) becomes a sub-linear function of E , i.e. the mobility starts to decrease with increasing E . As revealed by the early study for n-Si [21.117], in the range 10^3 – 10^5 V/cm, n does remain constant, but the mobility decreases appreciably, as seen Fig. 21.14. Further studies obtained, in addition, the following patterns: (e.g. [21.13, 14, 113]).

1. Drift velocity $v_d(E)$ is anisotropic in the orientation of E relative to the crystallographic axes: different values of v_d are obtained for the same E for E along different high-symmetry directions $\langle 111 \rangle$, $\langle 110 \rangle$ and $\langle 100 \rangle$. For less-symmetric directions v_d is not even parallel to E , which is known as the Sasaki–Shibuya effect [21.38]. The v_d – E relation depends strongly on T , as seen from Fig. 21.15a–b for the $\langle 111 \rangle$ and $\langle 100 \rangle$ directions. The anisotropy becomes stronger as T decreases, as seen from Fig. 21.16a–b. For electrons, the curves of v_d versus E for different T (Fig. 21.15a) tend to join together at some value of E , which increases with T , even though such a rejoining is not reached at all considered T . For holes (Fig. 21.15b), this tendency is much weaker and the rejoining field is much higher than for electrons.
2. For electrons at the highest $E \parallel \langle 111 \rangle$, a region where v_d is independent of E (saturation) is obtained (Fig. 21.15a). For holes, this type of saturation is not approached for all available E (Fig. 21.15b).
3. Ohm's law is reached at $T > 45$ K and 100 K for electrons and holes, respectively, and the results for mobility are in agreement with those obtained by standard techniques for the linear regime. At $T < 45$ K for electrons, and $T < 100$ K for holes, even at the lowest E , v_d is not linear with E . At low temperatures the mobility is as high as $5 \times 10^5 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$ at $E = 1.5 \text{ V/cm}$ for electrons ($T = 8 \text{ K}$), and $3.5 \times 10^5 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$ at $E = 3 \text{ V/cm}$ for holes ($T = 6 \text{ K}$). A negative differential mobility (NDM) was found with $E \parallel \langle 100 \rangle$ at $T < 40 \text{ K}$ for electrons (Fig. 21.16a). The field at which v_d reaches the maximum before the NDM region (NDM threshold), decreases with decreasing T . For holes, a net low-field saturation region of v_d ($50 \text{ V/cm} < E < 150 \text{ V/cm}$ at $T = 6 \text{ K}$) shows up for $E \parallel \langle 111 \rangle$, $\langle 110 \rangle$ and $\langle 100 \rangle$ (see top of Fig. 21.16b). This effect gradually disappears as T increases, and at $T > 38 \text{ K}$ it is no longer visible.

Fig. 21.16 (c) Summary of the data on the drift velocity obtained by different techniques. After [21.14] with permission. Holes, $T = 300$ K: *full* – time-of-flight [21.118], *dashed* – time-of-flight [21.119], *double-dot-dashed* – time-of-flight [21.120], *cross-dashed* – $I(V)$ in space-charge-limited current (SCLC) regime [21.121], *dot-dashed* – $I(V)$ [21.122], *arrow* – extrapolated value of v_{sh} [21.122]. Electrons, $T = 300$ K: *full* – time-of-flight [21.118], *long-dash-dot* – time-of-flight [21.119], *dashed* – time-of-flight [21.120], *double-dot-dash* – $I(V)$ in the SCLC regime [21.123], *dots* – $I(V)$ [21.124], *dash-crossed* – $I(V)$ [21.125], *dashed arrow* – v_{se} from $I(V)$ in avalanche diodes [21.126, 127]. Electrons, $T = 77$ K: *full* – time-of-flight [21.118], *dashed* – $I(V)$ [21.128], *dash-dot* – $I(V)$ [21.129], *dotted* – $I(V)$ [21.130, 131]

For electrons, the anisotropy is due to a repopulation of the valleys: when $E \parallel \langle 111 \rangle$ the six valleys (Fig. 21.3b) are equally oriented with respect to E and all of them give the same contribution to v_d . When, for example, $E \parallel \langle 100 \rangle$, two valleys exhibit the effective mass m_l in the direction of the field, while the remaining four exhibit the transverse mass $m_t < m_l$. Electrons in the transverse valleys respond with a higher mobility, are heated to a greater extent by the field and transfer electrons to the two longitudinal, *colder* and slower valleys, which results in a lower v_d than for $E \parallel \langle 111 \rangle$, as seen e.g. in Fig. 21.16a. For holes, the anisotropy is due to the two warped and degenerate valence sub-bands (Fig. 21.3c) resulting in different effective masses for holes with different k , and in the lowest and highest v_d for $E \parallel \langle 110 \rangle$ and $E \parallel \langle 100 \rangle$, as seen in Fig. 21.16b. A summary of the curves of v_d versus E is presented on Fig. 21.16c.

Anisotropy becomes stronger as T decreases, since a lower T leads to less-effective relaxation effects. In particular, at $T \approx 45$ K the repopulation of electron valleys may be so rapid with increasing $E \parallel \langle 100 \rangle$ that NDM occurs with E in the range 20–60 V/cm. NDM was observed via oscillations of the current [21.132], and in the I – V [21.128, 132, 133] and v_d – E ([21.113, 134, 135]) characteristics. Whether the

curves of electron v_d versus E for $E \parallel \langle 100 \rangle$ and $E \parallel \langle 111 \rangle$ join together at the high-field limit is still an open point. Theoretical considerations [21.136] seem to indicate that a small difference ($\approx 5\%$) between the two curves should remain. However, this difference is comparable to experimental error and merging of the two curves has been claimed at several temperatures in the experimental results [21.113, 118]. In the case of holes, both theoretical and experimental results [21.13] indicate that, up to the highest fields attained (5×10^4 V/cm), no merging occurs. The aforementioned anomalous behavior of the curves of v_d versus E for holes at low temperatures ($T < 38$ K) – that these curves tend to *saturate* at intermediate field strengths and then rise again – has been explained [21.13, 116] by a nonparabolic distortion of the heavy-hole spectrum.

A general tendency of $v_d(E)$ to saturate at the highest fields is an important phenomenon which was considered from the very beginning of the hot-electron investigations [21.137–139]. The original explanation [21.138] for this behavior was based on a rough physical model, in which it was assumed that the carriers emit an optical phonon as soon as they reach the energy $\hbar\omega_0$ of the phonon that limits the drift veloc-

Fig. 21.17 Measured versus simulation results on drift velocity in Si: (a) $v_{de}(E)$ at different indicated temperatures. Circles indicate experimental data by time-of-flight method, solid circle – $E \parallel \langle 111 \rangle$ and $E \parallel \langle 100 \rangle$, and lines Monte Carlo simulations results neglecting impurity scattering, full and broken – using six lowest and three allowed inter-valley phonons (Table 21.4), respectively. For $T \leq 45$ K, the theoretical curves which refer to the $\langle 100 \rangle$ direction are interrupted, as it was not possible to reach a sufficient precision in the simulated v_d . After [21.113, 114] with permission;

Fig. 21.17 (b) The $v_{de}(E)$ and $v_{dh}(E)$, for $E \parallel \langle 111 \rangle$, in high-purity Si at four different T . After [21.14] with permission, solid circle – the experimental data [21.118] and lines are the best-fit curves obtained with (21.32) using the parameters listed in Table 21.7;

Fig. 21.17 (c) $v_{se}(T)$ obtained experimentally with different techniques and numerically fitted. After [21.14] with permission, *solid circle* – time-of-flight [21.113, 114, 118, 142], *open circle* – $I(V)$ in the avalanche diodes [21.126, 127], *open triangle* – $I(V)$ in the SCLC regime [21.123]; the latter data have been normalized to $9.6 \times 10^6 \text{ cm s}^{-1}$ at 300 K; *line* represents the best fitting curve of (21.33)

Fig. 21.18 Diffusion coefficients of electrons versus E in Si at $T = 300 \text{ K}$. After [21.14] with permission: *solid circle* – $D_{||}$, time-of-flight data [21.113, 114]; *dashed* – $D_{||}$, noise data [21.143]; *crosses* – D_{\perp} , the geometrical technique data [21.144]; *full lines* – the Monte Carlo computed $D_{||}$ and D_E [21.113, 114]

ity by the saturation value $v_s \approx \sqrt{\hbar\omega_0/m^*}$ [21.138]. For electrons, inter-valley instead of optical phonons should be considered (Sect. 21.2.3). Subsequent calculations [21.140, 141] showed, that the Shockley formula should be considered only as a rough evaluation, since at very high electric field the transport process depends on many factors including several phonon dispersion curves, phonon emission and absorption, and non-

parabolic band corrections. Good agreement between the Monte Carlo calculations and the experimental data for high-purity n-Si is seen in Fig. 21.17a. In the case of holes the saturation was neither predicted theoretically, nor found experimentally. A nearly saturated drift velocity was observed [21.122] only at room temperature, and the saturation should occur, by extrapolation, at $E \geq 2 \times 10^5 \text{ V/cm}$ with v_{sh} around 10^7 cm/s (Fig. 21.16c).

Empirically adjusted formulas for $v_d(E)$ have been proposed for varying N_i and $T = 300 \text{ K}$

$$v_d = \frac{\mu_0 E}{\sqrt{1 + \frac{S(N_i/N_{ref})}{N_i/N_{ref} + S} + \frac{(E/E_1)^2}{E/E_1 + F} + (E/E_2)^2}} \quad (21.31)$$

[21.145], and for $N_i = 0$ and varying T

$$v_d = v_m \frac{E/E_c}{[1 + (E/E_c)^\beta]^{1/\beta}} \quad (21.32)$$

[21.108]; the best-fit parameters are presented in Table 21.7. Also a formula was suggested [21.14] for the electron saturated drift velocity as a function of temperature

$$v_{se}(T) = \frac{2.4 \times 10^7 \text{ cm/sec}}{1 + 0.8 \times \exp\left(\frac{600 \text{ K}}{T}\right)} \quad (21.33)$$

The applicability of (21.32) and (21.33) is clearly demonstrated by Figs. 21.17b and 21.17c, respectively.

Hot-Carrier Diffusion

Knowledge of diffusion processes is useful for a better understanding of charge-transport phenomena and correct simulation of high-frequency devices. At low fields the diffusion coefficient D is related to the mobility by the Einstein relation (Sect. 21.1.3). At high fields it becomes a field-dependent tensor, which describes the diffusion with respect to E depending on its direction in the crystallographic frame. The difference between diffusion parallel to and perpendicular to E is greater than the variations caused by changes in the crystallographic direction. Therefore, investigations set out to determine the field dependence of both the longitudinal ($D_{||}$) and transverse (D_{\perp}) components of the diffusivity tensor with respect to E irrespective of its orientation in the crystal.

The longitudinal diffusion coefficient can be measured by the Haynes–Shockley or time-of-flight [21.120] technique by observing the difference between the fall and rise times of the current pulse. This difference is caused by the spread of the carriers traveling across the

sample and is simply related to D_{\parallel} (e.g. [21.146]). Analogously, D_{\perp} can be obtained by observing the spread of the current perpendicular to the direction of the field. The current is originated by a point excitation on one surface of a Si wafer and is collected on the opposite surface by several electrodes of appropriate geometry [21.144]; this technique is sometimes called *geometrical* [21.14]. Finally, both D_{\parallel} and D_{\perp} have been related to noise measurements, parallel and perpendicular respectively to the current direction [21.143].

Figure 21.18 shows some experimental results on the field dependence of D_{\parallel} and D_{\perp} for electrons in Si at room temperature with $\mathbf{E} \parallel \langle 111 \rangle$. The data obtained by the noise measurements are in a reasonable agreement with the time-of-flight results, although the former cover a narrower range of \mathbf{E} , just outside Ohm's region. As \mathbf{E} increases D_{\parallel} decreases to about one third of its low-field value ($\approx 36 \text{ cm}^2/\text{s}$), which is in substantial agreement with theoretical Monte Carlo computations for the nonparabolic band [21.113]. The results for transverse diffusion showed that, as \mathbf{E} increases, D_{\perp} also decreases, but to a lesser extent than D_{\parallel} . There exists a hypothesis of validity to extrapolate the Einstein relation outside the linear region by $D_E = \frac{2E}{3q} \mu(E)$. As seen from Fig. 21.18, this yields a qualitative interpretation of D_{\perp} for not too high fields. As far as D_{\parallel} is concerned, the diffusion process seems much more complex than pictured by the Einstein relation. For holes, the dependence of D_{\parallel} on \mathbf{E} was found to be similar to that for electrons [21.14].

Impact Ionization

Impact ionization is an important charge-generation mechanism. It occurs in many silicon-based devices, either determining the useful characteristic of the device or causing an unwanted parasitic effect. The breakdown of a silicon p–n diode is caused by impact ionization if its breakdown voltage is larger than about 8 V. The operation of such devices as thyristors, impact avalanche transit time (IMPATT) diodes and trapped plasma avalanche-triggered transit (TRAPATT) diodes is based on avalanche generation, the phenomenon that results from impact ionization. The avalanche generation also plays an increasing role in degradation due to hot-carrier effects and bipolar parasitic breakdown of metal–oxide–semiconductor (MOS) devices, the geometrical dimensions of which have been scaled down recently.

The ionization rate is defined as the number of electron–hole pairs generated by a carrier per unit distance traveled in a high electric field, and is different for

electrons and for holes. Impact ionization can only occur when the particle gains at least the threshold energy for ionization from the electrical field. This can be derived from the application of the energy and momentum conservation laws to the amount $E_i \approx 1.5E_g$ (assuming that the effective masses of electron and hole are equal). A large spread of experimental values for E_i exists, with a breakdown field of order of $3 \times 10^5 \text{ V/cm}$. For more detailed consideration we refer the reader to the review article [21.147] noted in Sect. 21.2.3.

21.2.3 Review Material

The following materials may be recommended for further reading.

1. Electrical properties of Si [21.24]. Summary of papers on the subject that were published over a decade until 1965 are overviewed. Miscellaneous properties, such as piezoresistance and high-electric-field mobility, were also presented.
2. Electron mobility and resistivity in n-Si versus dopant density and temperature [21.148]. An improved model for computing μ_e as a function of N_d and T in uncompensated n-Si was formulated. The effects of electron–electron interaction on conventional scattering processes, as well as their anisotropies were incorporated empirically. The model was verified to $\pm 5\%$ of the mobility measured on wafers doped by phosphorous in the range $10^{13} - 10^{19} \text{ cm}^{-3}$.
3. Bulk charge-transport properties of Si [21.14]. Review of knowledge on the subject with special emphasis on application to solid-state devices. Most attention was devoted to experimental findings at room temperatures and to high-field properties. The techniques for drift-velocity measurements and the principles of Monte Carlo simulation were overviewed. Empirical expressions were given, when possible, for the most important transport quantities as functions of T , $N_{d(a)}$ and E .
4. Semi-empirical relations for the carrier mobilities [21.149]. From a review of different publications on $\mu_{e,h}$ in Si, the authors proposed an approximated calculation procedure, analogous to that of Li and Thurber, which permits a quick and accurate evaluation of $\mu_{e(h)}$ over a wide range of T , $N_{d(a)}$ and $n(p)$. The proposed relations are well adapted to device simulation since they allow short computation times.
5. Minority-carrier recombination in heavily doped silicon [21.150]. A review of understanding of

the recombination of minority carriers in heavily doped Si. A short phenomenological description of the carrier recombination process and lifetime was provided and the main theories of these were briefly reviewed with indications for their expected contributions in heavily doped Si. The various methods used for measuring the minority-carrier lifetime in heavily doped Si were described and critically examined. The insufficiency of existing theories to explain the patterns of lifetime versus doping was clearly demonstrated.

6. Minority-carrier transport modeling in heavily doped silicon emitters [21.111]. The experimental and theoretical efforts that addressed such important issues as: (i) the incomplete understanding of the minority-carrier physics in heavily doped Si, (ii) the lack of precise measurements for the minority-carrier parameters, (iii) the difficulties encountered with the modeling of transport and recombination in nonhomogeneously doped regions, and (iv) prob-

lems with the characterization of real emitters in bipolar devices, were reviewed with the goal of being able to achieve accurate modeling of the current injected into an arbitrarily heavily doped region in a silicon device.

7. Impact ionization in silicon: a review and update [21.147]. The multiplication factor and the ionization rate were revisited. The interrelationship between these parameters together with the multiplication and breakdown models for diodes and MOS transistors were discussed. Different models were compared and test structures were discussed to measure the multiplication factor accurately enough for reliable extraction of the ionization rates. Multiplication measurements at different T were performed on a BJT, and yielded new electron ionization rates at relatively low electric fields. An explanation for the spread of existed experimental data on ionization rate was given. A new implementation method for a local avalanche model into a device simulator was presented.

21.3 Optical Properties

21.3.1 Diversity of Silicon as an Optical Material

In *dielectric*-like material $n > k$ ($\varepsilon_1 > 0$), where for transparency and opacity it is necessary that $n \gg k$ ($\varepsilon_1 \gg \varepsilon_2$) and $n \approx k$ ($\varepsilon_1 \ll \varepsilon_2$), respectively (21.16). In *metallic*-like material $n < k$ ($\varepsilon_1 < 0$), where for good reflectivity and bad reflectivity it is necessary that $n \ll k$ ($|\varepsilon_1| \gg \varepsilon_2$) and $n \approx k$ ($|\varepsilon_1| \ll \varepsilon_2$), respectively. Since in Si ε depends on the wavelength and carrier concentration, it may exhibit all these types of optical behavior ranging from dielectric-like to metallic-like. For example, (111) undoped Si ($n = 2.3 \times 10^{14} \text{ cm}^{-3}$) at $\lambda = 0.62 \mu\text{m}$ behaves as a transparent dielectric, as $\varepsilon_1 = 15.254$ and $\varepsilon_2 = 0.172$ at that wavelength, while it is an opaque dielectric at $\lambda = 0.295 \mu\text{m}$, where $\varepsilon_1 = 2.371$ and $\varepsilon_2 = 45.348$. For heavily doped Si ($n = 10^{20} \text{ cm}^{-3}$), $n = 1.911$ and $k = 8.63$ at $\lambda = 16.67 \mu\text{m}$, so it behaves as a good metallic reflector while at $\lambda = 2 \mu\text{m}$, where $n = 3.47$ and $k = 6.131 \times 10^{-3}$ it is a transparent dielectric.

21.3.2 Measurements of Optical Constants

Various methods are used to measure the dielectric constant of single-crystalline Si including transmission,

reflection, and ellipsometric methods. For a smooth opaque sample, the quantity of interest is the complex reflection amplitude ρ_r (at normal incidence) defined by

$$\begin{aligned}\rho_r &= -\frac{\sqrt{\varepsilon} - 1}{\sqrt{\varepsilon} + 1}, \\ |\rho_r|^2 &= \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} = R_0, \\ \phi &= \arctan \frac{2k}{n^2 + k^2 - 1} = \arg(\rho_r), \\ &\text{mod } (\pi).\end{aligned}\quad (21.34)$$

The Fresnel reflectance spectrum $R_0(\omega)$ is measured using reflectometry. The KKR analysis also applies to the causal function $\ln(\rho_r) = \frac{1}{2} \ln R_0 + i\phi$ that gives

$$\phi(\omega) = \frac{1}{2\pi} \int_0^\infty \ln \left| \frac{\omega + \Omega}{\omega - \Omega} \right| \frac{d}{d\Omega} \ln R_0(\Omega) d\Omega. \quad (21.35)$$

With the $\psi(\omega)$ retrieved in this way, the last two relations in (21.34) are simultaneously solved to yield the n and k spectra. The KKR method requires, in principle, data over an infinite ω range, which are supplied by measurements over a confined range and an appeal to simple models for high and low frequencies. This limi-

Fig. 21.19 Refractive index n and the extinction coefficient k versus wavelength, using Adachi and Geist models in the wavelength ranges: (a) 0.2–0.45 μm ,

tation is avoided using optical measurements on smooth slabs.

For a slab of thickness d , the reflectance and transmittance at normal incidence are given by

$$R = R_0 \frac{1 - 2T_0 \cos 2\varphi + T_0^2}{1 - 2R_0 T_0 \cos 2\chi + R_0^2 T_0^2},$$

$$T = T_0 \frac{1 - 2R_0 \cos 2\psi + R_0^2}{1 - 2R_0 T_0 \cos 2\chi + R_0^2 T_0^2},$$

$$T_0 = e^{-\alpha d}, \quad (21.36)$$

where $\varphi = 2\pi nd/\lambda$ is the optical-path phase, $\chi = \varphi + \psi$ and $\alpha = 4\pi kd/\lambda$ is the power attenuation coefficient. The parameter αd characterizes the slab's opacity. At $n > k$ ($\varepsilon_1 > 0$, (21.17)), i.e. in the optically dielectric range, α is referred to as *absorption coefficient*. In the optically metallic range that exists for doped Si in the IR, where $k > n$ ($\varepsilon_1 < 0$, (21.17)), α^{-1} is the skin depth multiplied by a factor of ≈ 1 . If the dispersion of the optical constants is disregarded, R and T are periodic in $1/\lambda$ (21.20). For nonopaque slabs, these interference effects show up at $nd/\lambda > 1$. For thick slabs ($nd/\lambda \gg 1$), even small fluctuation of n or/and λ causes changes in φ of the order 2π . Therefore, if such factors as bulk defects, source incoherence and low spectral resolution are present in an experiment, then the averages of R and T over φ , given by

$$\langle R \rangle = R_0 (1 + T_0 \langle T \rangle),$$

$$\langle T \rangle = T_0 \frac{1 - 2R_0 \cos 2\psi + R_0^2}{1 - R_0^2 T_0^2}, \quad (21.37)$$

are more appropriate than (21.36). This *multiple-reflection approximation* [21.151] has proved effective

in countless studies. The apparent absorbance of the slab in the multiple-reflection approximation is calculated by

$$\langle A \rangle = 1 - \langle R \rangle - \langle T \rangle$$

$$= \frac{(1 - R_0)(1 - T_0) - 4R_0 T_0 \sin^2 \psi}{1 - R_0 T_0}. \quad (21.38)$$

^a Values calculated using an empirical fit [21.78], ^b values calculated using GDA [21.79]

Equation (21.38) at $k \ll n$ is extensively used in silicon-wafer thermometry [21.152, 153]. Given $\langle R \rangle$, $\langle T \rangle$ and d , (21.37) builds up a system of two equations for the two unknowns n and k . Thus, measurement of the reflection and transmission on the same slab of known thickness allows one to retrieve the optical constants. This R – T measurement method [21.154] is greatly simplified at $2k \ll n^2 + k^2 - 1$. Under this low-loss condition the above system can be solved analytically for T_0 and R_0 . The calculated T_0 directly yields k , and n is then found using the calculated R_0 . The R – T technique is the best method at $ad \leq 1$, while at $ad \gg 1$, where solving the aforementioned system becomes an ill-conditioned problem, the KKR analysis is more reliable. In two last decades, spectroscopic ellipsometry has gained wide recognition for being more precise than photometric methods. In ellipsometry, the ratio of reflectance for s - and p -polarized radiation, and the relative phase shift between

the two, are both measured at large angles of incidence [21.155].

The measured results are affected by the structural atomic-scale properties of the samples. These properties are defined by polishing processes – mechanical or chemical – that affect the surface damage and roughness, the properties of the surface native oxide, the growth mechanism of the measured layer, grain boundaries, and the quality of the cleaved surface. Since Si samples may be optically inhomogeneous, retrieving the optical constants from measurements may become a complicated inverse electromagnetic problem [21.156, 157], which is why some of the reported data for ε disagree by up to 30%. A detailed list of publications on the subject can be found in [21.158, 159]. Emphasis on these effects should be especially considered when transmission measurement is done for a wavelength range in which the absorption coefficient is large and thin samples are therefore required.

21.3.3 Modeling of Optical Constants

A method for calculating ε_1 and ε_2 and then n , k and α for photon energies of 0–6 eV ($\lambda > 0.2 \mu\text{m}$) has been reported [21.82]. The calculated data are in excellent agreement with experimental data for the wavelength range 0.2–4 μm [21.156, 160]. The model is based on the KKR (Sect. 21.1.3) and takes into

account the dependence of ε on the energy-band structure. It considers the effect of indirect-band-gap and inter-band transitions as well as the electron (conduction bands) and hole (valence bands) density of states. The fundamental absorption (generation of electron–hole pair) edge energy of 1.12 eV corresponds to the indirect transition from the highest valence band to the lowest conduction band. Sharp changes in the

^a Values calculated using an empirical fit [21.78], ^b values calculated using GDA [21.79]

optical constants are obtained at wavelengths around 0.367, 0.29 and 0.233 μm, which correspond to the energy-band critical points of 3.38, 4.27 and 5.317 eV, respectively. An additional analytical model for calculating the *n* and *k* values for the wavelength range 0.4–1.127 μm has been developed [21.158]. The model

is based on measured *k* and *n* data [21.161–163], where the calculated values are within ±10% of the measured values. Using Adachi and Geist models we have calculated and plotted *n*, *k*, ε₁ and ε₂ for the wavelength range 0.2–1.127 μm, as seen in Figs. 21.19 and 21.20.

Fig. 21.21 Optical constants versus wavelength at various electron concentrations using the GDA model. (a) Refractive index n .

Fig. 21.21 (b) Extinction coefficient k

In the IR range the lattice and free carriers, which arise from doping, give additive contributions. The free-carrier contribution to the dielectric function when the radiation quantum is much smaller than the mean electron energy, $\hbar\omega \ll \bar{E}$, is considered using the semiclassical Drude approximation (DA, Sect. 21.1.4), which leads to the simple formula

$$\varepsilon = \varepsilon_L - \frac{n_L^2 \omega_p^2}{\omega(\omega + i\gamma)}, \quad \gamma = \frac{1}{\tau}, \quad (21.39)$$

Fig. 21.22 Refractive index change versus wavelength at various electric fields [21.164]

where τ is the phenomenological relaxation time, ω_p is the electron plasma frequency given by

$$\omega_p = \sqrt{\frac{4\pi q^2 N}{\varepsilon_L m_c}}. \quad (21.40)$$

Here N denotes the carriers' concentration, $m_c \approx 0.26m_0$ for electrons (Table 21.2) and $m_c = (0.33-0.39)m_0$ for holes (Sect. 21.1.4).

Advanced GDA, which extrapolates the free-carrier contribution to the range of $\hbar\omega > \bar{E}$ was considered [21.79]. In Table 21.15 we tabulated the values of n and k for practical use at two extreme electron concentrations: 10^{16} cm^{-3} and 10^{20} cm^{-3} . The results placed in the columns headed by the abbreviation 'HW' were obtained using DA (21.21, 40, 41) and the empirically adjusted τ versus N fit [21.78]. The columns of theoretical values calculated by us using GDA are headed by the corresponding abbreviation. A disagreement between the theory and the empirical fit notable at heavy doping has been discussed in detail [21.79]. The dependencies of n and k on wavelength in the range at carrier concentration of $10^{16}-10^{20} \text{ cm}^{-3}$ in steps of 10 cm^{-3} are shown in Fig. 21.21.

21.3.4 Electric-Field and Temperature Effects on Optical Constants

It has been known for many years that the optical absorption spectrum of Si can also be affected by external electric fields (the Franz-Keldysh effect). The Franz-

Keldysh effect, which alters the α spectrum of crystalline Si, is field-induced tunneling between valence- and conduction-band states. In recent years, the generic term *electroabsorption* has been adopted for $\Delta\alpha$ versus E effects. The effect of electric field on the refractive index is shown in Fig. 21.22 [21.164]. Sharp changes occur around the wavelengths correspond to the band-gap transition.

The temperature dependence of the refractive index of high-purity damage-free Si, for photon energies less than 3 eV in the temperature range 300–500 K is given by [21.162]

$$\frac{\Delta n}{\Delta T} \approx 1.3 \times 10^{-4} n \quad (\text{K}^{-1}). \quad (21.41)$$

22. Silicon–Germanium: Properties, Growth and Applications

Silicon–germanium is an important material that is used for the fabrication of SiGe heterojunction bipolar transistors and strained Si metal–oxide–semiconductor (MOS) transistors for advanced complementary metal–oxide–semiconductor (CMOS) and BiCMOS (bipolar CMOS) technologies. It also has interesting optical properties that are increasingly being applied in silicon-based photonic devices. The key benefit of silicon–germanium is its use in combination with silicon to produce a heterojunction. Strain is incorporated into the silicon–germanium or the silicon during growth, which also gives improved physical properties such as higher values of mobility. This chapter reviews the properties of silicon–germanium, beginning with the electronic properties and then progressing to the optical properties. The growth of silicon–germanium is considered, with particular emphasis on the chemical vapour deposition technique and selective epitaxy. Finally, the properties of polycrystalline silicon–germanium are discussed in the context of its use as a gate material for MOS transistors.

22.1.1	Critical Thickness	482
22.1.2	Band Structure	483

Silicon–germanium ($\text{Si}_{1-x}\text{Ge}_x$) alloys have been researched since the late 1950s [22.1], but it is only in the past 15 years or so that these layers have been applied to new types of transistor technology. $\text{Si}_{1-x}\text{Ge}_x$ was first applied in bipolar technologies [22.2, 3], but more recently has been applied to metal–oxide–semiconductor (MOS) technologies [22.4–7]. This has been made possible by the development of new growth techniques, such as molecular-beam epitaxy (MBE), low-pressure chemical vapour deposition (LPCVD) and ultra-high-vacuum chemical vapour deposition (UHV-CVD). The key feature of these techniques that has led to the development of $\text{Si}_{1-x}\text{Ge}_x$ transistors is the growth of epitaxial layers at low temperatures (500–700 °C). This allows

$\text{Si}_{1-x}\text{Ge}_x$ layers to be grown without disturbing the doping profiles of structures already present in the silicon wafer. $\text{Si}_{1-x}\text{Ge}_x$ layers can be successfully grown on silicon substrates even though there is a lattice mismatch between silicon and germanium of 4.2%.

The primary property of $\text{Si}_{1-x}\text{Ge}_x$ that is of interest for bipolar transistors is the band gap, which is smaller than that of silicon and controllable by varying the germanium content. Band-gap engineering concepts, which were previously only possible in compound semiconductor technologies, have now become viable in silicon technology. These concepts have introduced new degrees of freedom in the design of bipolar transistors that have led to dramatic improvements in transistor

performance. In $\text{Si}_{1-x}\text{Ge}_x$ heterojunction bipolar transistors (HBTs), the $\text{Si}_{1-x}\text{Ge}_x$ layer is incorporated into the base and the lower band gap of $\text{Si}_{1-x}\text{Ge}_x$ than Si is used to advantage to dramatically improve the high-frequency performance. $\text{Si}_{1-x}\text{Ge}_x$ HBTs have been produced with values of cut-off frequency, f_T , approaching 300 GHz [22.8], a value unimaginable in silicon bipolar transistors. Values of gate delay well below 10 ps can be achieved in properly optimised $\text{Si}_{1-x}\text{Ge}_x$ HBTs [22.9]. In $\text{Si}_{1-x}\text{Ge}_x$ MOS field-effect transistors (MOSFETs), the $\text{Si}_{1-x}\text{Ge}_x$ layer is incorporated in the channel and is used to give improved values of mobility.

Initially, strained $\text{Si}_{1-x}\text{Ge}_x$ layers on silicon substrates were used to give improved hole mobility in p-channel transistors [22.7], but more recently thin, strained silicon layers on relaxed SiGe virtual substrates have been used to give improvements in both electron and hole mobility [22.4–6].

In this chapter, the properties of single-crystal silicon–germanium will first be outlined, followed by a description of the methods used for growing silicon–germanium layers. The properties and applications of polycrystalline silicon–germanium are also discussed later in the article.

22.1 Physical Properties of Silicon–Germanium

Silicon and germanium are completely miscible over the full range of compositions and hence can be combined to form $\text{Si}_{1-x}\text{Ge}_x$ alloys with the germanium content, x , ranging from 0 to 1 (0–100%). $\text{Si}_{1-x}\text{Ge}_x$ has a diamond-like lattice structure and the lattice constant is given by Vegard's rule:

$$a_{\text{Si}_{1-x}\text{Ge}_x} = a_{\text{Si}} + x(a_{\text{Ge}} - a_{\text{Si}}), \quad (22.1)$$

where x is the germanium fraction and a is the lattice constant. The lattice constant of silicon, a_{Si} , is 0.543 nm, the lattice constant of germanium, a_{Ge} , is 0.566 nm and the lattice mismatch is 4.2%.

When a $\text{Si}_{1-x}\text{Ge}_x$ layer is grown on a silicon substrate, the lattice mismatch at the interface between the $\text{Si}_{1-x}\text{Ge}_x$ and the silicon has to be accommodated. This

can either be done by compression of the $\text{Si}_{1-x}\text{Ge}_x$ layer so that it fits to the silicon lattice or by the creation of misfit dislocations at the interface. These two possibilities are illustrated schematically in Fig. 22.1. In the former case, the $\text{Si}_{1-x}\text{Ge}_x$ layer adopts the silicon lattice spacing in the plane of the growth and hence the normally cubic $\text{Si}_{1-x}\text{Ge}_x$ crystal is distorted. When $\text{Si}_{1-x}\text{Ge}_x$ growth occurs in this way, the $\text{Si}_{1-x}\text{Ge}_x$ layer is under compressive strain and the layer is described as *pseudomorphic*. In the second case, the $\text{Si}_{1-x}\text{Ge}_x$ layer is unstrained, or relaxed, and the lattice mismatch at the interface is accommodated by the formation of misfit dislocations. These misfit dislocations generally lie in the plane of the interface, as shown in Fig. 22.1, but dislocations can also thread vertically through the $\text{Si}_{1-x}\text{Ge}_x$ layer.

Fig. 22.1 Schematic illustration of pseudomorphic $\text{Si}_{1-x}\text{Ge}_x$ growth and misfit-dislocation formation

22.1.1 Critical Thickness

There is a maximum thickness of $\text{Si}_{1-x}\text{Ge}_x$ that can be grown before relaxation of the strain occurs through the formation of misfit dislocations. This is known as the critical thickness of the $\text{Si}_{1-x}\text{Ge}_x$ layer, and depends strongly on the germanium content, as shown in Fig. 22.2. The original calculations of critical layer thickness were made by *Matthews and Blakeslee* [22.11, 12] on the basis of the mechanical equilibrium of an existing threading dislocation. However, measurements of dislocation densities in $\text{Si}_{1-x}\text{Ge}_x$ showed, in many cases, no evidence of misfit dislocations for $\text{Si}_{1-x}\text{Ge}_x$ layers considerably thicker than the Matthews–Blakeslee limit. These results were explained by *People and Bean* [22.13] who calculated the critical thickness on the assumption that misfit-dislocation generation was determined solely by energy balance. The discrepancy between these two types of calculation can be explained by the observation that strain relaxation in $\text{Si}_{1-x}\text{Ge}_x$ layers occurs gradually. Layers above the People–Bean curve can be considered to be completely relaxed, whereas layers below the Matthews–Blakeslee curve can be considered to be fully strained. These fully strained layers are termed *stable* and will not relax during any subsequent high temperature processing. Layers lying between the two curves are termed *metastable*; these layers may be free of dislocations after growth, but are susceptible to relaxation during later high-temperature processing.

In practice, a number of additional factors influence the critical thickness of a $\text{Si}_{1-x}\text{Ge}_x$ layer. Of

particular importance to both $\text{Si}_{1-x}\text{Ge}_x$ HBTs and $\text{Si}_{1-x}\text{Ge}_x$ MOSFETs, is the effect of a silicon cap layer, which has been shown to increase the critical thickness of the underlying $\text{Si}_{1-x}\text{Ge}_x$ layer. Figure 22.3 shows a comparison of the calculated critical thickness as a function of germanium percentage for stable $\text{Si}_{1-x}\text{Ge}_x$ layers with and without a silicon cap. It can be seen that the critical thickness is more than doubled by the presence of the silicon cap.

The presence of misfit dislocations in devices is highly undesirable, since they create generation/recombination centres, which degrade leakage currents when they are present in the depletion regions of devices. Threading dislocations are also highly undesirable, as they can lead to the formation of emitter/collector pipes in $\text{Si}_{1-x}\text{Ge}_x$ HBTs. When designing $\text{Si}_{1-x}\text{Ge}_x$ devices, it is important that the $\text{Si}_{1-x}\text{Ge}_x$ thickness is chosen to give a stable layer, so that dislocation formation is avoided. A base thickness below the silicon cap curve in Fig. 22.3 will ensure a stable layer, which will withstand ion implantation and high-temperature annealing without encountering problems of relaxation and misfit-dislocation generation.

Considerable research has been done on the oxidation of $\text{Si}_{1-x}\text{Ge}_x$ [22.14, 15], and it has been found that the germanium in the $\text{Si}_{1-x}\text{Ge}_x$ layer does not oxidise, but piles up at the oxide/ $\text{Si}_{1-x}\text{Ge}_x$ interface. This pile-up of germanium makes it difficult to achieve low values of interface state density in oxidised $\text{Si}_{1-x}\text{Ge}_x$ layers. It is therefore advisable to avoid direct oxidation of $\text{Si}_{1-x}\text{Ge}_x$ layers, particularly in $\text{Si}_{1-x}\text{Ge}_x$ MOS technologies. In $\text{Si}_{1-x}\text{Ge}_x$ MOSFETs, a silicon cap is often

Fig. 22.2 Critical $\text{Si}_{1-x}\text{Ge}_x$ thickness as a function of germanium percentage (after *Iyer et al.* [22.2], copyright 1989 IEEE)

Fig. 22.3 Critical thickness as a function of germanium percentage for stable $\text{Si}_{1-x}\text{Ge}_x$ layers with and without a silicon cap (after *Jain et al.* [22.10], copyright 1992 Elsevier)

included above the $\text{Si}_{1-x}\text{Ge}_x$ layer that can be oxidised to create the gate oxide.

22.1.2 Band Structure

$\text{Si}_{1-x}\text{Ge}_x$ alloys have a smaller band gap than silicon partly because of the larger lattice constant and partly because of the strain. Figure 22.4 shows the variation of band gap with germanium percentage for strained and unstrained $\text{Si}_{1-x}\text{Ge}_x$. It can be seen that the strain has a dramatic effect on the band gap of $\text{Si}_{1-x}\text{Ge}_x$. For 10% germanium, the reduction in band gap compared with silicon is 92 meV for strained $\text{Si}_{1-x}\text{Ge}_x$, compared with 50 meV for unstrained $\text{Si}_{1-x}\text{Ge}_x$. The variation of band gap with germanium content for strained $\text{Si}_{1-x}\text{Ge}_x$ can be described by the following empirical equation:

$$E_G(x) = 1.17 + 0.96x - 0.43x^2 + 0.17x^3 \quad (22.2)$$

The band alignment for compressively strained $\text{Si}_{1-x}\text{Ge}_x$ on unstrained silicon is illustrated schematically in Fig. 22.5. This band alignment is referred to as *type I*, and the majority of the band offset at the hetero-

Fig. 22.4 Band gap as a function of germanium percentage for strained [22.16] and unstrained [22.1] $\text{Si}_{1-x}\text{Ge}_x$ (after Iyer et al. [22.2], copyright 1989 IEEE)

Fig. 22.5 Schematic illustration of the band alignment obtained for a compressively strained $\text{Si}_{1-x}\text{Ge}_x$ layer grown on an unstrained silicon substrate

Fig. 22.6 Valence- and conduction-band offsets as a function of germanium percentage for strained $\text{Si}_{1-x}\text{Ge}_x$ grown on unstrained silicon (after Poortmans et al. [22.17], copyright 1993 Elsevier)

junction interface occurs in the valence band, with only a small offset in the conduction band. Different band alignments can be obtained by engineering the strain in the substrate and the grown layer in different ways. For example, *type II* band alignments can be obtained by growing tensile-strained silicon on top of unstrained $\text{Si}_{1-x}\text{Ge}_x$. This arrangement gives large conduction- and valence-band offsets and is used in strained silicon MOSFETs.

Figure 22.6 shows the variation of valence-band offset, ΔE_V , conduction-band offset, ΔE_C , and band-gap narrowing, ΔE_G , with germanium content. It can be seen that the majority of the band offset occurs in the valence band. For example for 10% germanium, the valence-band offset is 0.073 eV, compared with 0.019 eV for the conduction-band offset. The conduction-band offset can therefore be neglected for most practical purposes.

22.1.3 Dielectric Constant

The dielectric constant of $\text{Si}_{1-x}\text{Ge}_x$ can be obtained by linear interpolation between the known values for silicon and germanium [22.17] using the following equation:

$$\epsilon(x) = 11.9(1 + 0.35x) \quad (22.3)$$

22.1.4 Density of States

While, the density of states in the conduction band in $\text{Si}_{1-x}\text{Ge}_x$ is generally assumed to be the same as that in silicon, there is some evidence in the literature to suggest that the density of states in the valence band

Fig. 22.7 Fermi-level position as a function of hole concentration for $\text{Si}_{1-x}\text{Ge}_x$ with four different germanium concentrations (after Iyer et al. [22.2], copyright 1989 IEEE)

Fig. 22.8 Ratio of density of states in the valence band for $\text{Si}_{1-x}\text{Ge}_x$ to that for Si as a function of germanium percentage (after Poortmans [22.20], copyright 1993 University of Leuven)

is considerably smaller. Manku and Nathan [22.18, 19] have calculated the E - k diagram for strained $\text{Si}_{1-x}\text{Ge}_x$ and shown that the density-of-states hole mass is significantly lower, by a factor of approximately three at 30% germanium. There is some experimental evidence to support this calculation. For example, freeze-out of holes in p-type $\text{Si}_{1-x}\text{Ge}_x$ has been reported to occur at higher temperatures than in p-type silicon [22.20] and enhancements in the majority-carrier, hole mobility have been reported for p-type $\text{Si}_{1-x}\text{Ge}_x$ [22.21].

Using the calculated values of hole density of states of Manku and Nathan [22.18, 19], the hole concentration can be calculated as a function of Fermi-level position.

These results are shown in Fig. 22.7 for $\text{Si}_{1-x}\text{Ge}_x$ with four different germanium contents. It can be seen that the Fermi level moves deeper into the valence band as the germanium concentration increases. Figure 22.8 shows the ratio of the calculated density of states in the valence

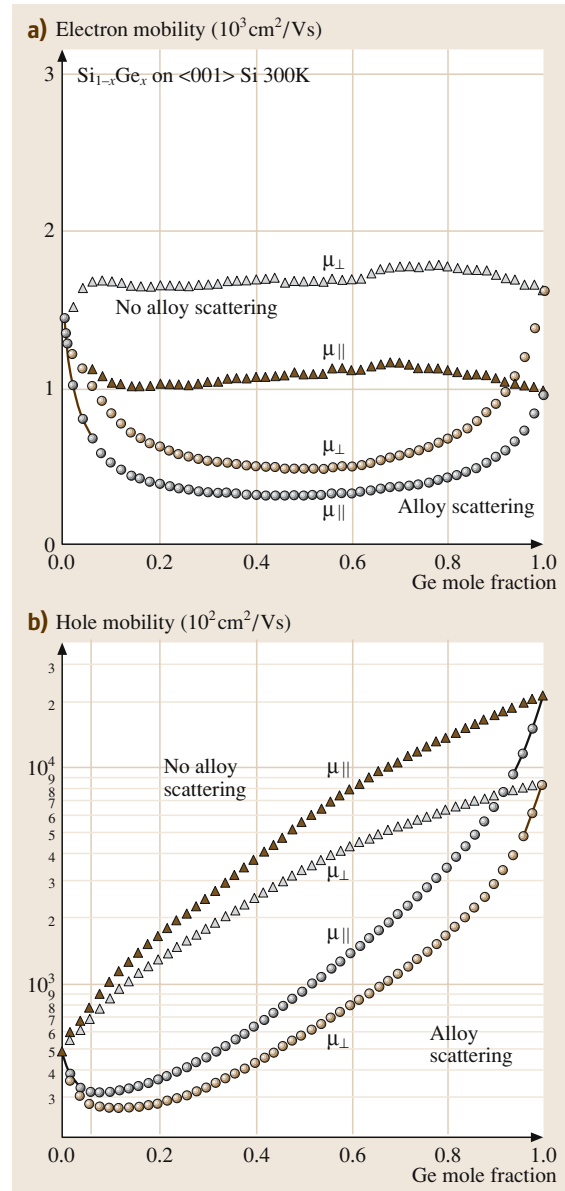

Fig. 22.9a,b Calculated 300-K electron (a) and hole (b) in-plane and out-of-plane low-field mobilities in strained $\text{Si}_{1-x}\text{Ge}_x$ grown on (100) Si (after Fischetti et al. [22.22], copyright 1996 American Institute of Physics)

band for $\text{Si}_{1-x}\text{Ge}_x$ to that for silicon as a function of germanium content. It is clear that the density of states in the valence band for $\text{Si}_{1-x}\text{Ge}_x$ is significantly lower than that for silicon at germanium contents of practical interest.

22.1.5 Majority-Carrier Mobility in Strained $\text{Si}_{1-x}\text{Ge}_x$

Values of in-plane and out-of-plane low-field mobility in strained $\text{Si}_{1-x}\text{Ge}_x$ grown on (100) Si have been calculated by Fischetti et al. [22.22], and are shown in Fig. 22.9. There is some uncertainty in the chosen values of alloy scattering parameters used in the calculations, but nevertheless the results are representative of current understanding. These results show a large enhancement of low-field hole mobility for $\text{Si}_{1-x}\text{Ge}_x$ compared with unstrained silicon, but only a modest enhancement of low-field electron mobility. These results indicate that strained $\text{Si}_{1-x}\text{Ge}_x$ channels can be used to significantly improve the mobility of p-channel MOSFETs, but little benefit is obtained for n-channel MOSFETs. For this reason, industry focus has moved away from channels realised in $\text{Si}_{1-x}\text{Ge}_x$ to channels realised in tensile-strained silicon, as discussed below.

22.1.6 Majority-Carrier Mobility in Tensile-Strained Si on Relaxed $\text{Si}_{1-x}\text{Ge}_x$

Tensile-strained silicon can be produced by growing a thin silicon layer on top of a relaxed $\text{Si}_{1-x}\text{Ge}_x$ virtual substrate. Figure 22.10 shows a typical virtual substrate for a surface-channel MOS transistor. A graded $\text{Si}_{1-x}\text{Ge}_x$ layer is grown on top of the silicon substrate with the Ge content varying from 0 to 30%. Misfit dislocations will form in this layer, but the majority of dislocations will be in the plane of the $\text{Si}_{1-x}\text{Ge}_x$ layer and only a small percentage will propagate vertically

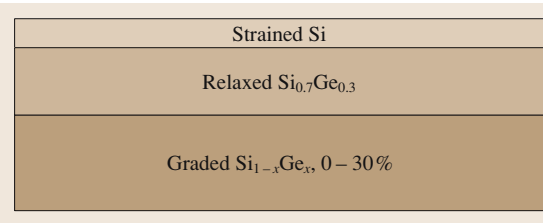

Fig. 22.10 Schematic illustration of a typical tensile-strained Si layer grown on top of a $\text{Si}_{1-x}\text{Ge}_x$ virtual substrate

Fig. 22.11 Effective electron mobility as a function of effective electric field for strained Si MOSFETs fabricated on a 30% $\text{Si}_{1-x}\text{Ge}_x$ virtual substrate (after Welser et al. [22.23], copyright 1994 IEEE)

to the surface of the layer. A 30%-relaxed $\text{Si}_{1-x}\text{Ge}_x$ buffer is then grown followed by a thin tensile-strained $\text{Si}_{1-x}\text{Ge}_x$ layer in which the channel is fabricated. The key to any virtual substrate growth process is the minimisation of dislocation propagation to the surface of the wafer.

Figure 22.11 shows typical values of effective electron mobility obtained from measurements on n-channel MOS transistors for a $\text{Si}_{1-x}\text{Ge}_x$ virtual substrate with 30% Ge [22.23]. For the surface-channel strained Si device, the effective mobility is enhanced by 80% compared with the Si control transistor due to the tensile strain in the $\text{Si}_{1-x}\text{Ge}_x$ layer.

Enhanced hole mobility can also be obtained in tensile-strained Si grown on a $\text{Si}_{1-x}\text{Ge}_x$ virtual substrate, though higher germanium contents are needed to obtain a significant mobility enhancement. Figure 22.12 shows typical values of effective hole mobility in strained Si for Ge contents between 35 and 50% [22.24]. The effective mobility of the strained Si device is enhanced by 100% compared with the Si control device.

22.1.7 Minority-Carrier Mobility in Strained $\text{Si}_{1-x}\text{Ge}_x$

$\text{Si}_{1-x}\text{Ge}_x$ HBTs are minority-carrier devices and hence values of the minority-carrier mobility of more interest than the majority-carrier mobility. Unfortunately very few measurements of minority-carrier mobility have been made in $\text{Si}_{1-x}\text{Ge}_x$. Poortmans [22.20] inferred values of minority-carrier mobility from measure-

Fig. 22.12 Effective hole mobility as a function of effective electric field for strained Si MOSFETs fabricated on a $\text{Si}_{1-x}\text{Ge}_x$ virtual substrate with Ge contents in the range 35–50% (after Leitz et al. [22.24], copyright 2002 IEEE)

Fig. 22.13 Measured values of the ratio of $N_C N_V D_{nb}$ in $\text{Si}_{1-x}\text{Ge}_x$ to that in Si as a function of acceptor concentration (after Poortmans [22.20], copyright 1993 University of Leuven)

ments on $\text{Si}_{1-x}\text{Ge}_x$ HBTs and found an enhancement in mobility compared with silicon by a factor of 1.2–1.4 for base doping concentrations in the range 5×10^{18} – $5 \times 10^{19} \text{ cm}^{-3}$. Given the scarcity of measured data on minority-carrier mobility and density of states in $\text{Si}_{1-x}\text{Ge}_x$, the most reliable way of calculating the expected gain improvement in a $\text{Si}_{1-x}\text{Ge}_x$ HBT is to use

data directly obtained from measurements on $\text{Si}_{1-x}\text{Ge}_x$ HBTs. The gain enhancement in a $\text{Si}_{1-x}\text{Ge}_x$ HBT is determined by the ratio of the product $N_C N_V D_{nb}$ in $\text{Si}_{1-x}\text{Ge}_x$ and Si, together with the band-gap narrowing due to the strained $\text{Si}_{1-x}\text{Ge}_x$. Figure 22.13 shows a graph of this $N_C N_V D_{nb}$ ratio as a function of acceptor concentration for three values of germanium content. It can be seen that for germanium contents of practical interest, in the range 11–16%, this ratio has a value of around 0.25.

22.1.8 Apparent Band-Gap Narrowing in $\text{Si}_{1-x}\text{Ge}_x$ HBTs

In $\text{Si}_{1-x}\text{Ge}_x$ HBTs, the apparent band-gap narrowing is often quoted, which combines the effect of the band-gap reduction and the effect of high doping. Poortmans et al. [22.17] have developed a theoretical approach that has been shown to be in reasonable agreement with experiment. Figure 22.14 shows the apparent band-gap narrowing in $\text{Si}_{1-x}\text{Ge}_x$ as a function of acceptor concentration for three values of germanium content. At low acceptor concentrations, the apparent band-gap narrowing in $\text{Si}_{1-x}\text{Ge}_x$ is slightly higher than that in silicon, but at acceptor concentrations in the range 1 – $2 \times 10^{19} \text{ cm}^{-3}$, the apparent band-gap narrowing is approximately the same. This latter doping range is the base doping range that is of practical interest for $\text{Si}_{1-x}\text{Ge}_x$ HBTs.

Fig. 22.14 Apparent band-gap narrowing as a function of acceptor concentration for $\text{Si}_{1-x}\text{Ge}_x$ with three different germanium concentrations (after Poortmans et al. [22.17], copyright 1993 Elsevier)

22.2 Optical Properties of SiGe

Interest in the optical properties of SiGe stems from the desire to design silicon-based optoelectronic devices as well as the usefulness of many optical techniques in material analysis. The optical properties of bulk SiGe provides an important starting point for any attempt at in-depth understanding, however, nearly all real applications of SiGe involve the use of thin, strained layers. Beyond this, the formation of SiGe quantum structures within silicon devices has remained one of the most promising methods by which device engineers hope to improve the largely unimpressive optical behaviour of silicon that is brought about by its indirect band gap. The growth of quantum wells, quantum wires and quantum dots in the Si/SiGe system has been extensively explored [22.26–31]. However, there has as yet been little success at using Si/SiGe quantum structures to produce efficient silicon-based light emitters, although there have been impressive attempts [22.31]. Perhaps the most promising devices based on SiGe quantum wells are near-infra-red photodetectors in which the SiGe can be used to enhance sensitivity at the optical-communications wavelengths [22.32–36]. More

futuristic applications of SiGe quantum wells include devices based on transitions between the confined energy levels in quantum wells. Devices based on these *inter-subband* transitions include quantum-well infrared photodetectors (QWIPs) [22.37, 38] and quantum cascade lasers [22.39, 40].

22.2.1 Dielectric Functions and Interband Transitions

A range of 1- μm -thick $\text{Si}_{1-x}\text{Ge}_x$ films grown by MBE on Si(100) substrates have been studied by spectroscopic ellipsometry to yield their complex dielectric functions at room temperature [22.25]. Both the real (ϵ_1) and imaginary (ϵ_2) parts of the measured dielectric function for Ge compositions of 0, 0.2, 0.4, 0.6, 0.8 and 1.0 are shown in Fig. 22.15a and b, respectively.

In Fig. 22.15b the absorption structures observed at 3.4 and 4.2 eV in the spectra shown for silicon originate from direct band-to-band transitions at various regions in the Brillouin zone of silicon. The structure seen around 3.4 eV is due to E'_0 , E_1 and $E_1 + \Delta_1$ interband transition

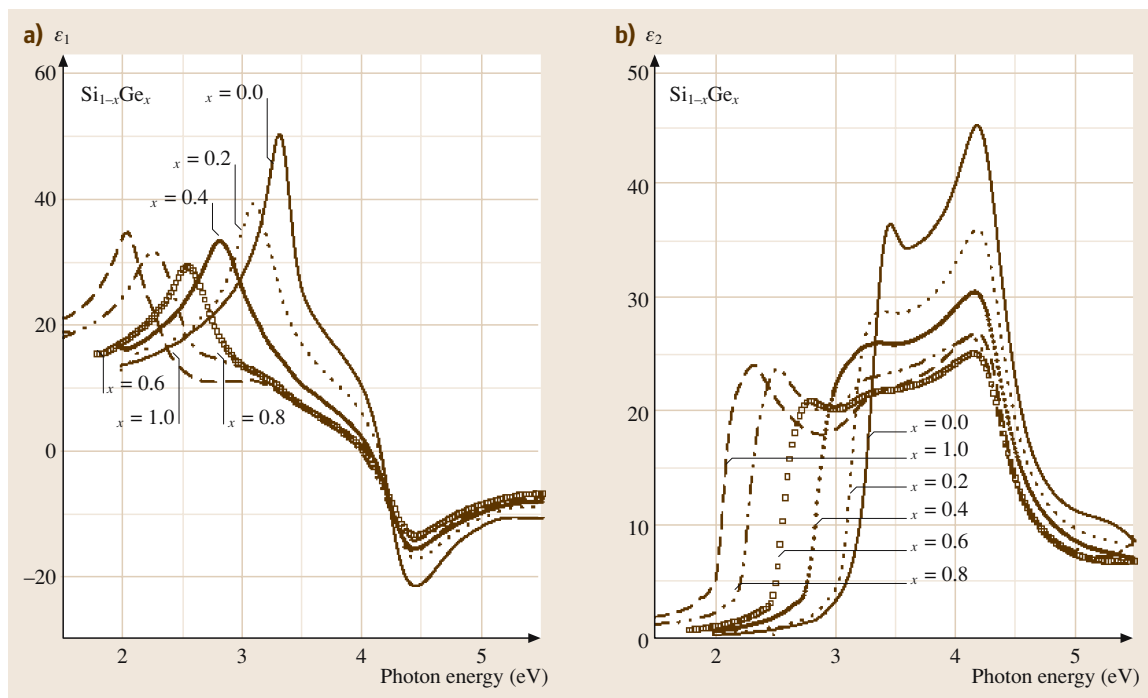

Fig. 22.15a,b Real (a) and imaginary (b) parts of the dielectric functions of relaxed $\text{Si}_{1-x}\text{Ge}_x$ alloys with composition x indicated in the legend (after Bahng et al. [22.25], copyright 2001, American Physical Society)

Fig. 22.16 Evolution of E'_0 , E_1 , $E_1 + \Delta_1$, $E_2(X)$ and $E_2(\Sigma)$ transition energies for relaxed $\text{Si}_{1-x}\text{Ge}_x$ with composition x (after Bahng et al. [22.25], copyright 2001, American Physical Society)

edges, whereas the structure at 4.2 eV is due to $E_2(X)$ and $E_2(\Sigma)$ edges [22.25]. The evolution of each of these transition edges for the full range of SiGe compositions is shown in Fig. 22.16.

The quadratic fits shown in Fig. 22.16 are as follows [22.25]:

$$E'_0(x) = 3.337 - 0.348x + 0.222x^2 \quad (22.4)$$

$$E_1(x) = 3.398 - 1.586x + 0.27x^2 \quad (22.5)$$

$$E_1 + \Delta_1(x) = 3.432 - 1.185x + 0.065x^2 \quad (22.6)$$

$$E_2(X)(x) = 4.259 - 0.052x + 0.084x^2 \quad (22.7)$$

$$E_2(\Sigma)(x) = 4.473 - 0.139x + 0.072x^2 \quad (22.8)$$

22.2.2 Photoluminescence

The emission properties of semiconductor structures are of fundamental interest to scientists as well as being an important analytical technique for engineers. In general, the features of low-temperature photoluminescence spectra are very dependent on the specific conditions under which materials are grown and treated. This is because emission energies and emission rates are often sensitive to even small variations of impurity or defect densities, as well as variations in strain or composition. A brief examination of low-temperature

photoluminescence spectra is nearly always sufficient to allow a simple qualitative assessment of material quality; alternatively, detailed analysis can permit a broad range of material or structural parameters to be assessed or determined. No two photoluminescence spectra are the same. In this section and the section that follows on photoluminescence studies of Si/SiGe quantum wells, we will present a range of spectra that represent most of the key features that have been observed.

Weber and Alonso [22.41] have provided a very useful study of the near-band-gap photoluminescence of bulk SiGe alloys. In their study bulk SiGe samples are cut from nominally undoped polycrystalline ingots prepared by a zone-leveiling technique. Figure 22.17 shows the photoluminescence spectra for a range of compositions. Samples were excited using the 514-nm line of an argon ion laser and the sample temperature was 4.2 K.

Fig. 22.17 Near-band-gap photoluminescence spectra for several bulk SiGe samples (after Weber et al. [22.41], copyright 1989, American Physical Society)

Excitonic emission lines are a strong feature of photoluminescence spectra when the thermal energy of the semiconductor is less than the exciton binding energy. Each spectrum featured in Fig. 22.17, across the full range of SiGe compositions, show similar *excitonic* features.

In most spectra the most pronounced peak is the no-phonon (X^{NP}) line caused by the optical recombination of excitons bound to shallow impurities. In the case of the no-phonon line, momentum is conserved through interaction with the binding impurity. There are many candidate atoms for these shallow impurities and with B, P and As having binding energies of 4.2, 5.0 and 5.6 meV, respectively [22.42]. These bound energy states will tend to dominate luminescence spectra for doped samples and will always tend to be present in nominally undoped samples. The no-phonon line is accompanied by transverse-optical (X^{TO}) or transverse acoustic (X^{TA}) phonon replicas that are created as photon emission is accompanied by the momentum-conserving creation of lattice vibrations in Si–Si, Si–Ge or Ge–Ge bonds.

Figure 22.18 shows how the spectrum from a bulk $Si_{0.915}Ge_{0.085}$ sample develops with increasing temperature [22.41]. With increasing temperature the X^{NP} line thermalises to leave the free-exciton (FE^{NP}) line. Here, emission from nominally free excitons is greatly enhanced for the alloy samples by local fluctuations in composition that provide momentum-conserving scattering centres [22.43].

Fig. 22.18 Photoluminescence spectra of a bulk $Si_{0.915}Ge_{0.085}$ sample at different temperatures (after Weber et al. [22.41], copyright 1989, American Physical Society)

Fig. 22.19 Photoluminescence spectra of a bulk $Si_{0.42}Ge_{0.58}$ sample at different temperatures (after Weber et al. [22.41], copyright 1989, American Physical Society)

At higher temperatures the free-exciton line is also thermalised and all fine structure is lost, at temperatures around 25 K broad luminescence bands are commonly observed (Fig. 22.19 [22.41]). These deep luminescence bands are difficult to assign and have been ascribed to impurities, structural defects and, as in the case of the line presented in Fig. 22.19, potential wells formed by alloy fluctuations [22.41].

Weber and Alonso [22.41] use their data to provide analytical expressions for both the X^{NP} and L bands for bulk $Si_{1-x}Ge_x$ in the range $0 \leq x \leq 0.85$ as follows:

$$E_{gx}^{(x)}(x) = 1.155 - 0.43x + 0.206x^2 \text{ eV} \quad (22.9)$$

$$E_{gx}^L(x) = 2.010 - 1.270x \text{ eV} \quad (22.10)$$

At low temperatures narrow excitonic luminescence features are indicative of defect-free material, and in this way low-temperature photoluminescence becomes a good qualitative tool with which material quality can be assessed.

22.2.3 SiGe Quantum Wells

Figure 22.20 shows the first excitonic luminescence spectra from a Si/SiGe multiple quantum well grown by atmospheric-pressure CVD [22.28]. As we can see, many of the features seen in the photoluminescence spectra of quantum-well samples are similar to

Fig. 22.20 Excitonic photoluminescence spectrum of a SiGe quantum well (after Grutzmacher et al. [22.28], copyright 1993, AVS)

those seen from the bulk samples described in the previous section. Again, the most pronounced peak is the no-phonon (NP) line and this is accompanied by phonon replicas, including, impressively, a two-phonon replica of the NP line ($\text{TO} + \text{TO}^{\text{Si-Si}}$). The most significant difference between bulk and quantum well spectra is the energy positions of the excitonic features as these are shifted by quantum confinement effects.

Robbins et al. [22.26], have provided one of the most detailed studies of near-band-gap photoluminescence from pseudomorphic SiGe layers and provide analytical expressions for all factors pertaining to the energy positions of the excitonic energy gap for $\text{Si}_{1-x}\text{Ge}_x$ quantum wells in the range $0 < x < 0.24$. The effects of alloying, confinement, band offsets, alignment type and exciton binding energy are all taken into account. Samples used in the study were grown by low-pressure CVD at 920 °C; a typical set of photoluminescence spectra are shown in Fig. 22.21.

The exciton band gap at 4.2 K is considered for thick (50-nm) strained layers (E_X^S) where the energies are not affected by quantum shifts, the following expression is derived:

$$E_X^S(x) = 1.155 - 0.874x + 0.376x^2 \text{ eV}, \quad (x < 0.25) \quad (22.11)$$

Here the presence of strain is responsible for the differences from the expression obtained for bulk samples (22.9). An expression for the exciton binding energy $E_B^C(x)$ is theoretically derived for the cubic alloy and the following quadratic expression is fitted:

$$E_B^C(x) \approx 0.0145 - 0.022x + 0.020x^2 \text{ eV}, \quad (x < 0.25) \quad (22.12)$$

A strain-corrected expression is also provided but this is found to modify (22.12) only slightly. Thus by adding (22.11) and (22.12) an expression for the band gap can be obtained.

$$E_C - E_V \approx 1.17 - 0.896x + 0.39x^2 \text{ eV}, \quad (x < 0.25) \quad (22.13)$$

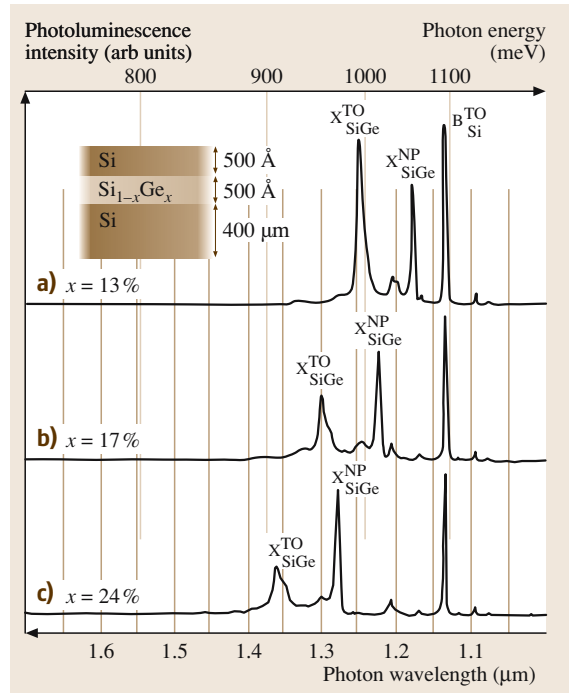

Fig. 22.21 4.2-K photoluminescence spectra from layers with the nominal structure shown in the inset (514-nm Ar-ion laser excitation) (after Robbins et al. [22.26], copyright 1992, American Physical Society)

22.3 Growth of Silicon–Germanium

Over the past ten years and more there have been rapid developments in techniques for the growth of Si and $\text{Si}_{1-x}\text{Ge}_x$ epitaxial layers at low temperatures. This has been made possible by a number of changes in the design of epitaxy equipment and by improvements to growth processes. There are two main prerequisites for the growth of epitaxial layers at low temperature:

- Establishment of a clean surface prior to growth [22.44–47]
- Growth in an ultra-clean environment [22.48–50]

The removal of oxygen and carbon is the main problem in establishing a clean surface prior to growth. A clean silicon surface is highly reactive and oxidises in air even at room temperature. The secret of low-temperature epitaxial growth is therefore the removal of this native oxide layer and the maintenance of a clean surface until epitaxy can begin. Two alternative approaches to pre-epitaxy surface cleaning have been developed, as described below.

22.3.1 In-Situ Hydrogen Bake

The concept that underlies this surface clean is the controlled growth of a thin surface oxide layer, followed by its removal in the epitaxy reactor using a hydrogen bake. The controlled growth of the surface oxide layer is generally achieved using a Radio Corporation of America (RCA) clean [22.44] or a variant [22.45]. The oxide created by the RCA clean is removed in the reactor using an in-situ bake in hydrogen for around 15 min at a temperature in the range 900–950 °C. The temperature required to remove the native oxide depends on the thickness of the oxide, which is determined by the severity of the surface clean.

22.3.2 Hydrogen Passivation

An alternative approach to pre-epitaxy cleaning is to create an oxide-free surface using an ex-situ clean and then move quickly to epitaxial growth before the native oxide can grow. The aim of the ex-situ clean is to produce a surface that is passivated by hydrogen atoms bonded to dangling bonds from silicon atoms on the surface. When the wafers are transferred in the epitaxy reactor, the hydrogen can be released from the surface of the silicon very quickly using a low-temperature bake or even in the early stages of epitaxy without any bake. Meyerson [22.46] has reported that hydrogen desorbs

at 600 °C at a rate of a few monolayers per second, so the hydrogen passivation approach allows epitaxial layers to be grown at low temperatures without the need for a high-temperature bake. The hydrogen-passivated surface is stable for typically 30 min after completion of the ex-situ cleaning [22.47].

22.3.3 Ultra-Clean Epitaxy Systems

Having produced a clean hydrogen-passivated silicon surface, it is clearly important to maintain the state of this surface in the epitaxy system. This necessitates the use of low-pressure epitaxy systems if epitaxial growth at low temperatures is required. Figure 22.22 summarises the partial pressures of oxygen and water vapour that need to be achieved in an epitaxy system if an oxide-free surface is to be maintained at a given temperature [22.48, 49]. This figure shows that epitaxial growth at low temperature requires low partial pressures of oxygen and water vapour, which of course can be achieved by reducing the pressure in the epitaxy system. Research [22.50] has shown that a pressure below 30 Torr is needed to achieve silicon epitaxial growth below 900 °C.

22.3.4 $\text{Si}_{1-x}\text{Ge}_x$ Epitaxy

The growth of $\text{Si}_{1-x}\text{Ge}_x$ epitaxial layers can be achieved over a wide range of temperatures using low-pressure chemical vapour deposition (LPCVD) [22.50] or ultra-high-vacuum chemical vapour deposition (UHV-CVD) [22.51, 52]. The gas used to introduce the germanium into the layers is germane, GeH_4 . The influence of germanium on the growth rate is complex, as illustrated in Fig. 22.23. At temperatures in the range 577–650 °C a peak in the growth rate is seen. At low germanium contents, the growth rate increases with germanium content, whereas at high germanium content, the growth rate decreases with germanium content. In the low-temperature regime it has been proposed that hydrogen desorption from the surface is the rate-limiting step. In $\text{Si}_{1-x}\text{Ge}_x$ this occurs more easily at germanium sites than at silicon sites and hence the growth rate increases with germanium content [22.37]. As the germanium content increases, the surface contains more and more germanium and less and less hydrogen. The rate-limiting step then becomes the adsorption of germane or silane. Robbins [22.53] proposed that the sticking coefficient for germane or silane was lower at germanium sites. This would slow the adsorption rate as the ger-

Fig. 22.22 Conditions for oxide formation in an epitaxy system. Note that 1 atm = 1.113 bar = 760 Torr = 1.113×10^5 Pa (after Smith and Ghidini [22.48, 49], copyright Electrochemical Society 1984)

Fig. 22.23 Growth rate of $\text{Si}_{1-x}\text{Ge}_x$ as a function of germanium percentage for temperatures in the range 577–750 °C (after Racanelli et al. [22.54], copyright 1990, American Institute of Physics)

manium content increased and hence slow the growth rate.

22.3.5 Selective $\text{Si}_{1-x}\text{Ge}_x$ Epitaxy

Selective epitaxy is the growth of a single-crystal layer in a window, with complete suppression of growth elsewhere, and can be achieved in a number of different ways. The most common method of achieving both selective Si and $\text{Si}_{1-x}\text{Ge}_x$ epitaxy is by introducing chlorine or HCl into the growth chamber. This can either be

done by adding chlorine or HCl as a separate gas or by using a growth gas that contains chlorine, for example dichlorosilane, SiH_2Cl_2 . With chlorine chemistry, selective growth of silicon and $\text{Si}_{1-x}\text{Ge}_x$ can be achieved to both silicon dioxide and silicon nitride.

Chlorine is reported to have two effects that lead to selective growth. First it increases the surface mobility of silicon and germanium atoms, so that atoms deposited on the oxide or nitride layer are able to diffuse across the surface to the window where the growth is occurring. Second it acts as an etch [22.50] and hence can remove silicon or germanium atoms deposited on the oxide or nitride. The strength of the etching action increases with chlorine content and, if the chlorine content is too high, etching of the substrate will occur instead of epitaxial growth.

A typical growth process for selective silicon epitaxy would use silane and a few percent of HCl [22.50]. The growth rate for this process is shown in Fig. 22.24, and compared with the growth rate for dichlorosilane and silane epitaxy. It can be seen that the activation energy for the silane-plus-HCl process is very similar to that for the dichlorosilane process, indicating that the growth mechanisms are similar. One disadvantage of chlorine-based growth processes over the silane process is a lower growth rate at low temperatures, as can clearly be seen in Fig. 22.24. It is also possible to grow silicon selectively using dichlorosilane and HCl [22.55].

Selective $\text{Si}_{1-x}\text{Ge}_x$ growth is generally easier to achieve than selective silicon growth, as illustrated in

Fig. 22.24 Silicon growth rate as a function of reciprocal temperature for three different growth gases: 40 sccm of SiH_4 , 80 sccm of dichlorosilane and 20 sccm of SiH_4 with 2 sccm of HCl. The hydrogen flow was 2 slm (after Regolini et al. [22.50], copyright 1989 American Institute of Physics)

Fig. 22.25 Germanium percentage as a function of germane: dichlorosilane (DCS) flow ratio for temperatures in the range 500–650 °C showing the move from nonselective to selective growth as the proportion of germane in the gas flow increases (after *Zhong et al.* [22.56], copyright 1990, American Institute of Physics)

Fig. 22.25 [22.56] for $\text{Si}_{1-x}\text{Ge}_x$ growth using germane and dichlorosilane. The growth moves from nonselective to selective as the proportion of germane in the gas flow increases.

Arrhenius plots for $\text{Si}_{1-x}\text{Ge}_x$ growth using germane and dichlorosilane are shown in Fig. 22.26 for $\text{Si}_{1-x}\text{Ge}_x$ layers grown using germane and dichlorosilane and for two different HCl flows. It can be seen that the growth rate decreases and the activation energy increases with increasing HCl flow. The explanation proposed for this behaviour is that the limiting growth mechanism changes from hydrogen desorption from the growing surface to chlorine or HCl desorption from the surface [22.57]. This decrease in growth rate at high HCl flows is a disadvantage because it leads

Fig. 22.26 Arrhenius plots for $\text{Si}_{1-x}\text{Ge}_x$ growth at two different HCl flow rates. The dichlorosilane and germane flow rates were fixed at 100 and 8 ml/min respectively (after *Kiyota et al.* [22.57], copyright 2002, IEEE)

to increased growth times. High HCl flows can also cause surface roughening when the $\text{Si}_{1-x}\text{Ge}_x$ layer is heavily boron-doped [22.57]. These considerations demonstrate that the HCl flow should be chosen to be to the smallest value that is consistent with good selective epitaxy.

Silane can be used for selective silicon epitaxy if the growth is performed at a high temperature. This approach relies on the fact that nucleation of growth on oxide is more difficult than that on silicon. This incubation time for growth on an oxide layer is relatively long at high temperatures but much shorter for growth at low temperatures. Selective silicon layers 1 μm thick can be grown using silane at a temperature of 960 °C [22.58], but the achievable layer thickness decreases with decreasing temperature. At 800 °C the maximum selective silicon layer thickness is around 130 nm, at 700 °C it is around 60 nm, and at 620 °C it is around 40 nm. Selective growth to silicon dioxide can be achieved using silane only, but not to silicon nitride.

22.4 Polycrystalline Silicon–Germanium

In the past ten years there has been increasing interest in polycrystalline silicon–germanium for a number of applications that require polycrystalline material deposition at low temperature (around 600 °C). Examples of potential applications are thin film transistors, gates of MOS transistors and polySiGe emitters for SiGe HBTs.

In thin-film transistor technologies [22.59–61], polycrystalline silicon–germanium is compatible with the low-thermal-budget processing that is needed to produce thin-film devices for large-area electronics. The key physical property of polycrystalline silicon–germanium that makes it attractive is its lower melting point than silicon. This means that processes such as deposition,

Fig. 22.27 Band-energy levels in silicon, silicon–germanium and germanium

Fig. 22.28 Work-function difference between a polySi_{1-x}Ge_x gate and an n-type substrate as a function of germanium content (after King et al. [22.60], copyright 1994, IEEE)

crystallisation, grain growth and dopant activation will occur at a lower temperature than in silicon. Thus lower temperature processes can be used for polySiGe devices and hence it is preferable to polySi in applications with tight thermal-budget requirements.

In MOS transistors, polycrystalline silicon–germanium is attractive as a gate material for future generations of MOS transistor, since the germanium content in the silicon–germanium layer can be varied by 200–300 mV in the direction of a mid-gap gate [22.63–65]. This can be understood from Fig. 22.27, which compares the conduction- and valence-band energy levels in single-crystal silicon, silicon–germanium and germanium. Silicon and germanium have similar

electron affinities (4.05 and 4.00 eV respectively), but germanium has a much smaller band gap (0.66 eV compared with 1.12 eV). The energy difference between the valence band and the vacuum level is therefore about 0.5 eV smaller in germanium than in silicon. In silicon–germanium, this energy difference can be varied by varying the germanium content. This allows the threshold voltage of p-channel MOS transistors to be tuned by varying the germanium content in the polySi_{1-x}Ge_x gate.

Figure 22.28 shows values of work-function difference between the polySi_{1-x}Ge_x gate and the n-type silicon substrate as a function of germanium content in a polySi_{1-x}Ge_x gate [22.60]. The work function is defined as the difference in energy between the vacuum level and the Fermi level. In p⁺ polySi_{1-x}Ge_x the Fermi level is near the valence band and hence the work-function difference varies strongly with germanium content. In n⁺ polySi_{1-x}Ge_x the Fermi level is near the conduction band and hence the work-function difference varies little with germanium content.

In Si_{1-x}Ge_x HBTs, polySi_{1-x}Ge_x has potential as an emitter of a SiGe HBT [22.62]. In bipolar transistors, the breakdown voltage, BV_{CEO} , is inversely proportional to the gain [22.66] and hence transistors with a high gain have lower values of breakdown voltage. Si_{1-x}Ge_x HBTs inherently have high values of the gain because the reduced band gap of the Si_{1-x}Ge_x base enhances the collector current. The base current is unchanged by the Si_{1-x}Ge_x base and hence the gain, which is the

Fig. 22.29 Use of a polySi_{1-x}Ge_x emitter to vary the base current of a Si_{1-x}Ge_x HBT and hence give the best trade-off between gain and breakdown voltage BV_{CEO} . (after Kunz et al. [22.62], copyright 2003, IEEE)

ratio of collector current to base current, is increased. The use of a polySi_{1-x}Ge_x emitter instead of a polySi emitter provides a reduced band gap in the emitter, which enhances the base current, and thereby reduces the gain. Typical measured values of base current in a polySi_{1-x}Ge_x emitter are shown in Fig. 22.29, where it can be seen that 19% germanium gives a factor of approximately four reduction in gain. A polySi_{1-x}Ge_x emitter therefore allows the gain to be tuned to give the best trade-off between gain and breakdown voltage BV_{CEO} .

22.4.1 Electrical Properties of Polycrystalline Si_{1-x}Ge_x

Figure 22.30 shows the sheet resistance as a function of anneal temperature for boron- and phosphorus-doped Si_{1-x}Ge_x for different germanium contents. For boron-doped polySi_{1-x}Ge_x the sheet resistance decreases with increasing germanium content, with the decrease being large between 0 and 25% germanium and smaller between 25 and 50% germanium. In contrast, for phosphorus-doped polySi_{1-x}Ge_x the sheet resistance

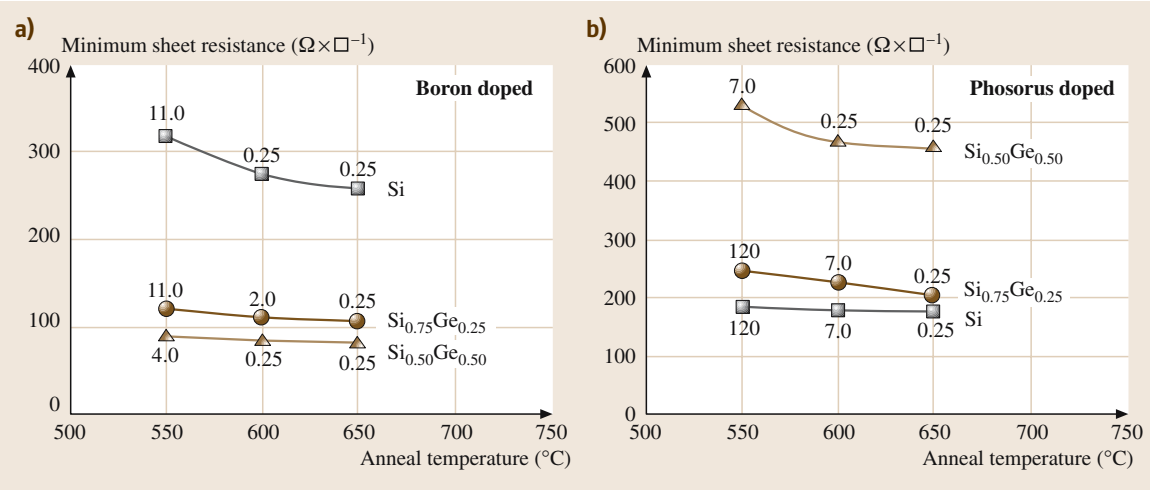

Fig. 22.30 Sheet resistance as a function of anneal temperature for boron- and phosphorus-doped polycrystalline Si_{1-x}Ge_x with various germanium contents (after Bang et al. [22.67], copyright 1995, American Institute of Physics)

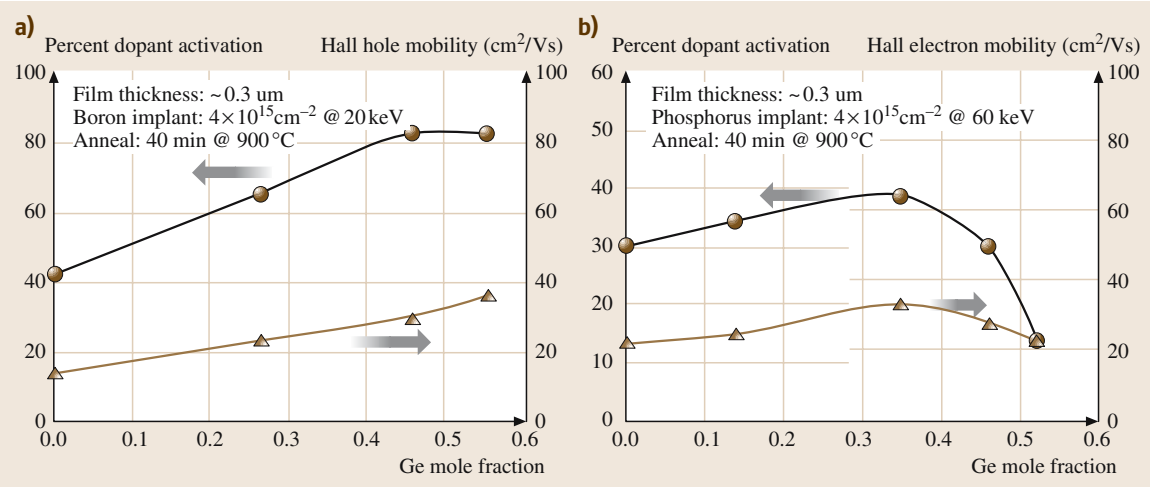

Fig. 22.31 Percentage dopant activation and Hall hole mobility as a function of germanium content for boron- and phosphorus-doped polySi_{1-x}Ge_x (after King et al. [22.60], copyright 1994, IEEE)

increases with increasing germanium content, with the increase being small between 0 and 25% germanium and large between 25 and 50%. Similar behaviour is seen for arsenic-doped polySi_{1-x}Ge_x where higher values of sheet resistance have been reported for polySi_{1-x}Ge_x than for polySi [22.64].

The explanation for the sheet-resistance results in Fig. 22.30 can be found in Fig. 22.31, which shows the results of Hall measurements [22.60]. For boron-doped polySi_{1-x}Ge_x both the activation and the Hall mobility increase with increasing germanium content, thereby explaining the decrease in sheet resistance with

increasing germanium content. For phosphorus-doped polySi_{1-x}Ge_x there is little change in activation and electron mobility at low germanium contents, but a sharp decrease in activation at germanium contents above 35%. This explains the sharp increase in sheet resistance seen in Fig. 22.30 for germanium contents between 25 and 50%. The decrease in activation at high germanium contents in the phosphorus-doped polySi_{1-x}Ge_x may be due to increased segregation at grain boundaries. Boron does not generally segregate to grain boundaries [22.68], which may explain the different behaviour in boron- and phosphorus-doped polySi_{1-x}Ge_x.
